Preface to the Fourth Edition

Globalization and global warming are the terms of our times and include a daily constant and extremely rapid transportation of millions of humans and animals, plants, food, and goods over often far distances from one region of the world to any other and back. This has increased the likelihood of a broad and intensive import and export of parasites, their vectors, and/or transmitted agents of diseases, which may give rise to the local endemics arising worldwide or even pandemics of considerable impact for human and animal health and all related economic factors. Thus there are no more tropical diseases that can be avoided by not entering such countries. Today we have traveler's disease, we have local zoonoses, and we have diseases due to imported animals and plants. The latter may have severe consequences in countries where such diseases had been absent up to now since the people, animals, and plants have not had the chance to develop immunity or other means of protection.

Therefore, we are aware that the knowledge in the field of parasitology – especially in transmission, diagnosis, and treatment – must be kept at a high level and up to date in order to fight a parasitosis, from wherever, as quickly and effectively as possible.

The presentation of our fourth edition of the *Encyclopedia of Parasitology* contributes to these goals in several ways. The number of keywords has been considerably increased, their contents include important new knowledge gained since 2008, and perception of the facts has been ameliorated by adding more tables, more figures, and an even closer connection by setting more links from one keyword to another. The quick and effective finding of updated information in human, veterinary, and biological aspects of parasitology is offered by more than 40 contributors, all of whom are well-known specialists in their field of research and who are all active in cooperation with their governments in the daily fight against the diseases deriving from parasitic infections of all kinds.

The fourth edition is presented in three volumes, sorted A–Z, and in an online version, both of which make it easy for all users to obtain the needed information within a minimum of time.

I am very grateful to all coauthors for their intensive, quick reviewing and careful updating of their keywords. I also wish to express my thanks to the readers of the third edition for their broad acceptance of our book, since the complete selling of this edition made it possible to publish the present edition after such a short period.

I hope that our most recent efforts are as well accepted as those of the first three editions and that the readers of our books and the users of our online version have the same benefits as the authors in the fight against parasites and their vectors.

For the authors
Prof. Dr. H. Mehlhorn (Editor)

Preface to the First Edition

Although in recent decades many methods have been developed to control parasitic diseases of humans and animals, chemoresistance and reduction of budgets for control have caused the problems to increase worldwide. Efforts in the “struggle against parasites” must be redoubled if we are not to become overwhelmed by human health problems and problems of food production. This absolute need has led to the application of various new methods to classical parasitology. Thus the different fields of parasitological research are at present expanding so rapidly that it is impossible for an individual to follow the main problems and to evaluate and recognize recent progress.

The purpose of this book is to give a comprehensive review of the facts and trends in veterinary and human parasitology, through contributions from distinguished specialists in different fields. The authors have focused their contributions on the most important and promising results, in a way which it is hoped will inform students, teachers, and researchers (zoologists, veterinarians, physicians) about those topics, which may be far from their own working fields, but knowledge of which may be necessary to develop new ideas. Thus, all chapters, the length of which will surely change in future editions, are provided with references opening the literary entrance to each field of research.

We hope that the book will be fruitful and lead to the establishment of new ideas, trends, and techniques in the struggle against parasites.

Ruhr-Universität Bochum, FRG
Bochum, January 1988

For the authors
Prof. Dr. H. Mehlhorn (Editor)

Preface to the Third Edition

Globalization is the term of our time, and includes a daily constant and extremely rapid transportation of millions of humans and animals, plants, foods, and goods over often far distances from one region of the world to any other and back.

This, of course, has increased the likelihood of a broad and intensive import and export of parasites, their vectors and/or transmitted agents of diseases, which may give rise to the local endemics arising worldwide or even pandemics of considerable impact for human and animal health and all related economic factors. Thus there are no more tropical diseases, which can be avoided by not entering such countries. Today we have traveler's disease, we have local zoonoses, and we have diseases due to imported animals and plants. The latter may have severe consequences in countries where such diseases had been absent up to now since the people, animals, and plants have not had the chance to develop immunity or other means of protection. An example is the Blue-tongue-virus-disease of ruminants – transmitted by ceratopogonid blood-suckers, which in summer 2006 was apparently imported (inside game animals) from South Africa to Central Europe and has spread within a few months in the Netherlands, Belgium, Northern France, and wide regions of Germany seriously harming the rearing of cattle and sheep.

Therefore, we are aware that the knowledge in the field of parasitology – especially in transmission, diagnosis, and treatment – must be kept at a high level and up to date in order to fight a parasitosis, from wherever, as quickly and effectively as possible.

The presentation of our third edition of the Encyclopedia of Parasitology contributes to these goals in several ways. The number of keywords has been increased by about 30 %, their contents include important new knowledge gained since 2001, and perception of the facts has been ameliorated by adding 20 % more tables, more figures, and an even closer connection by setting more links from one keyword to another. The quick and effective finding of updated information in human, veterinary, and biological aspects of parasitology is offered by more than 40 contributors, all of whom are well-known specialists in their fields of research, and who are all active in cooperation with their governments in the daily fight against the diseases deriving from parasitic infections of all kinds.

The third edition is presented as two volumes, sorted A to Z, and in an online version, both of which make it easy for all users to obtain the needed information within a minimum of time.

I am very grateful to all coauthors for their intensive, quick reviewing and serious updating of their keywords. I also wish to express my thanks to the readers of the second edition for their broad acceptance of our book, since the complete selling of this edition made it possible to publish the present edition after such a short period.

I hope that our most recent efforts are as well accepted as with the first two editions, and that the readers of our book and the users of our online version have the same benefit as the authors, when working on our parasitologic topics.

Acknowledgments

No one could write a book such as this without the help of many people including our close coworkers. Their material and comments were helpful while selecting and preparing the contributions to this book. We are especially grateful to those colleagues who contributed one or several micrographs:

- Prof. Dr. G. Brugerolle, Clermont-Ferrand
- Prof. Dr. J.F. DeJonckheere, Brussels
- Prof. Dr. I. Desportes, Paris
- Prof. Dr. J. Grüntzig, Düsseldorf
- Prof. Dr. I. Ishii, Japan
- Prof. Dr. K. Hausmann, Berlin
- Prof. Dr. A.O. Heydorn, Berlin
- Prof. Dr. S. Klimpel, Frankfurt
- Prof. Dr. M. Køie, Copenhagen
- B. Mehlhorn, Neuss
- Prof. Dr. H. Palm, Kiel
- Prof. Dr. S. Saem, Teheran
- Prof. Dr. E. Schein, Berlin (†)
- Dr. J. Schmidt, Düsseldorf
- Prof. Dr. J. Schrével, Paris
- Prof. Dr. Schuster, Dubai
- Prof. Dr. Y. Yoshida, Kyoto

All other micrographs are either from the authors of the particular chapter or from the editor.

The editor and the authors would like to thank Mrs. I. Schaefer and Miss S. Walter for carefully typing large parts of the manuscript, Mr. S. Köhler and Dipl.-Ing. I. Mehlhorn for their excellent preparation of the micrographs, and Mrs. B. Mehlhorn for correcting the proofs. The beautiful hand drawings were produced by the late Fried Theissen (Essen) and Dr. Volker Walldorf (Düsseldorf).

Furthermore we would like to thank the publishers at Springer for their cooperation and generous support of our efforts to produce an optimum outline of parasitology.

Authorships of Articles in the Present Text Without Author Addresses

The nonpersonally named authors of keywords of the here included articles of the first three editions are contributed by the following persons:

- Acanthocephala (Taraschewski, Karlsruhe)
- Antibodies (Seitz and Reiter-Owona, Bonn)
- Arboviruses (Aspöck, Vienna and Dobler, Munich)
- Behavior (Taraschewski, Karlsruhe)
- Cell penetration (Dubremetz, Montpellier)
- Chemotherapy against helminthoses (Raether, Frankfurt and Harder, Leverkusen)
- Chemotherapy against protozoan diseases (Raether and Hänel, Frankfurt)
- Classification (Mehlhorn, Düsseldorf)
- Clinical and pathological signs of parasitic infections in domestic animals (Vercruysse, Ghent; de Bont, Ghent and Dauschies, Leipzig)
- Clinical and pathological signs of parasitic infections in man (Frenkel, Kansas and Mehlhorn, Düsseldorf)
- Connecting entries (Mehlhorn, Düsseldorf)
- Drug action in ectoparasites (Turberg and Londershausen, Leverkusen)
- Drug action in protozoa and helminths (Harder, Leverkusen)
- Drug tables (Raether, Frankfurt)
- Ecological aspects (Combes, Perpignan)
- Ectoparasitizides (Londershausen and Hansen, Leverkusen)
- Environmental aspects (Combes, Perpignan)
- Epidemiological aspects (Wernsdorfer, Vienna)
- Eye parasites (Mehlhorn, Düsseldorf)
- Fine structure of parasites (Mehlhorn, Düsseldorf)
- Hormones (Spindler, Ulm)
- Host finding mechanisms (Haas, Erlangen)
- Host parasite interface (Dubremetz, Montpellier and Mehlhorn, Düsseldorf)
- Immunodiagnostic methods (Seitz and Reiter-Owona, Bonn)
- Immunological responses of the host (Gessner and Röllinghoff, Erlangen)
- Insects as vectors (Schaub, Bochum)
- Life cycles (Mehlhorn and Walldorf, Düsseldorf)
- Lyme disease (Spielman, Boston; Armstrong, Boston and Mehlhorn, Düsseldorf)

- Mathematical models (Freeman, Boston and Lehmacher, Cologne)
- Metabolism (Köhler, Zurich and Tielens, Utrecht)
- Molecular systematics (Mackenstedt, Hohenheim)
- Morphology (Mehlhorn, Düsseldorf)
- Motility (Dubremetz, Montpellier and Mehlhorn, Düsseldorf)
- Nerves-structures and functions (Gustafsson, Abo and Maule, Belfast)
- Novel drugs (Kayser and Julsing, Dortmund)
- Nutrition (Köhler, Zurich and Tielens, Utrecht)
- Opportunistic agents, except *Pneumocystis* (Mehlhorn, Düsseldorf)
- Pathologic effects in animals (Vercruysse, Ghent; de Bont, Ghent and Dagschies, Leipzig)
- Pathologic effects in humans (Frenkel, Kansas and Mehlhorn, Düsseldorf)
- Pathology (Frenkel, Kansas and Mehlhorn, Düsseldorf)
- Pentastomida (Walldorf, Düsseldorf)
- Phylogeny (Mackenstedt, Hohenheim)
- Physiological aspects (Köhler, Zurich and Tielens, Utrecht)
- Planning of control (Wernsdorfer, Vienna)
- *Pneumocystis* (Kaneshiro and Smulian, Cincinnati)
- Reproduction (Mehlhorn, Düsseldorf)
- Resistance against drugs (Harder, Leverkusen)
- Serology (Seitz and Reiter-Owona, Bonn)
- Strategy of control measurements (Wernsdorfer, Vienna)
- Ticks as vectors in animals (Mehlhorn, Düsseldorf)
- Ticks as vectors in humans (Spielman, Boston; Armstrong, Boston and Mehlhorn, Düsseldorf)
- Ultrastructure (Mehlhorn, Düsseldorf)
- Vaccination
 - Protozoa (Behr and Pereira da Silva, Paris)
 - Plathelminthes (Richter, Berlin)
 - Nematelminthes (Schnieder, Hannover)
- Vector biology
 - Insects (Schaub, Bochum and Mehlhorn, Düsseldorf)
 - Ticks (Spielman and Mehlhorn, Düsseldorf)

About the Editor

Prof. Dr. Heinz Mehlhorn Curriculum Vitae

Private

30.09.1944	Born in Aussig/Elbe, Germany
1964–1971	Studies in Bonn (Biology, Chemistry)
1973	Married with Birgit
	3 children: Martin, Isabelle, Tim
	1 grandson: Henry

Career

1971	PhD Natural Sciences, Bonn University
1975	Habilitation Düsseldorf University
1977	Professor for Parasitology, Düsseldorf
1984	Professor for Parasitology, Bochum
1987–1992	Dean University Bochum
1995–2009	Professor for Parasitology, Düsseldorf University
2000–	Founder and CEO of Research Company Alpha-Biocare, Düsseldorf, Germany

Honors

- Aaronson Price Award, German Government
- Leuckart Medal, German Society of Parasitology

- Member of the Academy of Science
- Honoring Medal of the Japanese Government
- Remembrance Medals King Saud University, Riyadh; Cairo University
- Reviewer Excellence Centers Japan, Australia, Saudi Arabia
- President German Society of Parasitology
- World President Protozoology
- Steering Board of World Society of Parasitology
- Guest professorships: Japan, Egypt, France, Saudi Arabia, China

Scientific Output

- 26 patents on antiparasitic drugs
- 25 books
- 250 original papers
- Since 1987: Chief Editor of *Parasitology Research*
- Yearly television and radio broadcasts on parasitological topics
- Since 1987 more than 150 PhD students: 27 are professors today (in several countries)

A

Abamectin

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Chemical Class

Macrocyclic lactone (16-membered macrocyclic lactone, avermectins).

Mode of Action

Glutamate-gated chloride channel modulator
nematocidal drugs and ► [ectoparasitocides](#) –
[antagonists and modulators of chloride channels](#).

Abbreviata

Genus of physalopteroid nematodes in amphibians, reptiles, and a few mammals.

Abdominal Pain

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Leading symptom in some parasitic infections (Angiostrongyliasis costaricensis, Ascariasis in children, ► [Capillariasis](#), Dipylidiasis, ► [Echinococciasis](#), ► [Gnathostomiasis](#), Strongyloidiasis, Taeniasis, Toxocariasis, and Trichuriasis).

Ablepsia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Greek: blindness.

Aboimisas

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Genus name used as synonym for *Haemaphysalis punctata*.

Abundance

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name: Latin, *abundantia* = richness

This term describes the amount of agents of diseases or vectors of parasites in a given biotope or in an infected individual.

Abortion

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Premature expulsion of an embryo or a nonviable fetus caused by parasitic infections, e.g., with ► *Toxoplasma gondii*, ► *Neospora caninum* (syn. ► *Hammondia heydorni*), ► *Trypanosoma* species, and ► *Tritrichomonas foetus*.

Acalculous Cholecystitis

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Symptom due to infections of gall bladder, e.g., by *Encephalitozoon intestinalis*, and ► *Opisthorchis species*.

Abscess

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Inflammatory reactions around foci of parasites within hosts (e.g., *Angiostrongylus*, ► *Leishmania*, ► *Entamoeba histolytica*). ► *Pathology*.

Acalyptratae

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Family of brachyceran insects comprising the families Braulidae (► *Braula coeca*) and Carnidae, belonging to the so-called Muscomorpha.

Acanthamoeba castellanii

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Species of facultatively parasitic ► [amoebae](#); ► [Acanthamoebiasis](#); ► [Opportunistic agents](#); ► [GAE](#).

Infectious legionellae or other bacteria and viruses may be transported by such amoebae in biofilms. For life cycle see ► [Amoebae](#).

Acanthamoeba Keratitis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Sight-threatening infection of the eye due to opportunistic *Acanthamoeba* spp., which excrete proteases that degrade basement membranes and induce cytolysis as well as apoptosis of corneal cells. This finally culminates in the dissolution of the collagenous corneal stroma.

Acanthamoebiasis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Acanthamoeba spp. have been found in the throat; mouth pipetting of fluids into cell culture has

given rise to contaminated cell cultures in numerous instances. In the throat the ► [amoebae](#) appear to be nonpathogenic. However, in patients with long-standing immunosuppression, tissue invasion does occur, usually leading to ► [encephalitis](#) which is fatal and occasionally to focal lesions elsewhere. The inflammation is mononuclear, partially in response to necrosis of brain tissue, and is sometimes stated to be granulomatous; hemorrhage may be marked. Large amoebic ► [trophozoites](#) and smaller cysts with an irregular “corrugated” wall are found in the lesions. Often the ► [amoebae](#) (Figs. 1 and 2) are difficult to distinguish from macrophages; the latter have intensely staining nuclei, whereas the amoebae have vesicular nuclei and a “foamy” ► [cytoplasm](#). The inflammatory reaction is of course variable because of immunosuppression of the patients (► [Pathology](#)). The amoebae are not found in the spinal fluid. Patients with acquired immunodeficiency syndrome (► [AIDS](#)) showed invasion of the nasopharynx with *Acanthamoeba* spp. Other sites of involvement by *Acanthamoeba* spp. are the cornea, skin, and lung; especially in the eyes, *Acanthamoeba* stages are rather common in persons using plastic lenses. Thus, these species are not only ► [opportunistic agents](#).

Main Clinical Symptoms

Chronic brain disturbances and possibly granulomatous encephalitis (► [GAE](#)); eye – conjunctivitis, keratitis, and uveitis.

Incubation Period

1 day–2 weeks.

Prepatent Period

1 day–2 weeks.

Acanthamoebiasis, Fig. 1 Developmental stages of *Naegleria* and *Acanthamoeba* species, which are facultatively pathogenic. *CV* contractile vacuole, *CW* cyst wall,

EC external cyst wall, *EN* inner cyst wall, *FP* filopodium, *F* flagellum, *LP* lobopodium, *N* nucleus, *OS* ostiole, *P* pore, *U* uroid, posterior end

Acanthamoebiasis, Fig. 2: Light micrograph of a trophozoite of *Acanthamoeba* sp. Note the characteristic filament-like pseudopodia

Diagnosis

Culture techniques.

Prophylaxis

Do not swim in eutrophic lakes; change fluids for contact lenses often.

Therapy

► [Treatment of opportunistic agents.](#)

Acanthella

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The name acanthella (Figs. 1 and 2) has been attributed to the ► **Acanthocephalan** stage between the ► **acanthor** and the larva that is infective to the final (or paratenic) host (► **Cystacanth**, ► **Acanthocephala**). Its growth begins under the serosa of the intermediate host and continues in its body cavity. The morphological changes from the ► **acanthor** that has survived the enclosure by the intermediate host's hemocytes and detached itself from the intestinal wall to the late acanthella and the “► **cystacanth**” are considerable, e.g.,

organogenesis occurs as well as a rotation of the worm's axis through 90°, while the ► **tegument** of the acanthor becomes stretched to form the acanthella's tegument. First, the central nuclear mass begins to split into different bodies which become the primordia of the organs.

The acanthella's tegument shows remarkable differentiation during the development in the arthropod's hemocoel. Its outer membrane forms microvilli-like protuberances (Fig. 1, page 3) that build up a membranous spongelike envelope around the larva. Hemocytes can be found in it (Fig. 1), especially near early acanthellae and if the intermediate host is not entirely suitable. Later on the spongy vesicular cover becomes supplemented by a thin interior and an exterior layer of amorphous matter and detaches itself from the worm body, forming a gap of different width with an electron lucent granular matrix (probably liquid), Fig. 2 (page 4). Late acanthellae show everted proboscis; finally the ► **proboscis** becomes invaginated or the entire presoma as well as the posterior end is retracted, so that the larva appears in a cystlike shape (► **Cystacanth**). This shape is common among species with definitive hosts that chew or grind their food in their upper intestinal tract (Fig. 2).

Acanthella, Fig. 1 Transmission electron micrograph of the outer part of a young acanthella and the surrounding spongy envelope (SE) of microvilli-like outgrowths of the larva's surface. This envelope has not yet detached.

A hemocyte (HC) of the intermediate host (a beetle) has invaded the envelope and come close to the worm with its ► **pseudopodia** (arrows); N nucleus of the hemocyte, SL ► **striped layer** of the developing tegument, ×3,500

Acanthobdella peledina

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek, *acantha* = spike, *bdella* = leech; Latin, *peledinus* = dark.

Species of blood-sucking leeches of the family Acanthobdellidae, which parasitizes on fish (e.g., salmonids) in freshwater. The individuals of this species reach a length of up to 3.5 cm and are (as the other members of this group) characterized by hooks at the four bristles of the first five segments. This makes them looking like the systematically related polychaetes within the common phylum Annelida. These hooks apparently have similar functions as the anterior sucker, which, however, lacks in this species. While practically all other leeches are subdivided inside in 32 segments, *A. peledina* is an exception, since this species possesses only 29 inner segments. However, when seen from the outside, much more ringlike structure becomes visible, since about 2–14 outer rings correspond – depending on the species – to a single inner segment. In the case of *A. peledina*, however, each segment has strictly 4 bristles.

Name

Greek: *acantha* = thorn, *cephale* = head.

Classification

Phylum or lower group of ► [Metazoa](#).

Order: Oligacanthorhynchida

Family: Oligacanthorhynchidae

Genus: ► [Macracanthorhynchus](#)

Genus: *Prosthenorchis*

A

General Information

Adult members of the Acanthocephala are highly specialized heterosexual, intestinal parasites that take up nutrition parenterally since they have no intestine. Vertebrates are used as final (definitive) hosts, arthropods as intermediate hosts (Table 1). The body consists of two major parts, the ► [praesoma](#) and the ► [metasoma](#). The ► [praesoma](#) comprises the ► [proboscis](#), armed with a set of specific hooks (Fig. 1, Attachment), a more or less pronounced neck, the ► [proboscis](#) receptacle, and the two lemnisci (Figs. 2 and 3), which are cylindrical appendages of the praesomal ► [tegument](#). The tube-shaped metasoma (= trunk) is bounded by a solid body wall, enclosing the pseudocoel, which in addition to liquid is mainly filled with male or female sexual organs.

Additional morphological features as well as biological characteristics determine the affiliation to one of the classes.

System

Class 1: Archiacanthocephala Meyer 1931: species have terrestrial life cycles; mammals or birds are final hosts, and insects (or millipedes) intermediate hosts; in addition, paratenic hosts are often involved; main longitudinal vessels of the lacunar system run dorsally and ventrally; usually there are eight uninucleate ► [cement glands](#); few tegumental nuclei; ligament sacs inside the pseudocoel, also in adult worms (Fig. 3). The well known orders are:

Order: Apororhynchida

Order: Gigantorhynchida

Order: Moniliformida

Family: Moniliformidae

Genus: *Moniliformis*

Class 2: Palaeacanthocephala Meyer 1931: mostly aquatic life cycles; fish (waterbirds, seals) are final hosts, crustaceans intermediate hosts; main vessels of the lacunar system run laterally; two to eight multinucleate cement glands; numerous tegumental nuclei; ligament sacs ruptured in adult worms.

Order: Echinorhynchida

Family: Echinorhynchidae

Genus: ► [Acanthocephalus](#)

Genus: *Echinorhynchus*

Family: Pomphorhynchidae

Genus: *Pomphorhynchus*

Order: Polymorphida

Family: Centrorhynchidae

Family: Plagiorhynchidae

Family: Polymorphidae

Genus: *Corynosoma*

Genus: *Filicollis*

Genus: *Polymorphus*

Class 3: Eoacanthocephala Van Cleave, 1936: aquatic life cycles; fish (also reptiles, amphibians) are final hosts, and small crustaceans (mostly Ostracoda) intermediate hosts; main vessels of the lacunar system run dorsally and ventrally, only a single, giant uninucleate cement gland; tegument with giant nuclei; ligament sacs generally persistent in adults.

Order: Gyraacanthocephala

Order: Neoechinorhynchida

Family: Neoechinorhynchidae

Genus: ► [Neoechinorhynchus](#)

Family: Tenuisentidae

Genus: *Paratenuisentis*

Recently, a fourth class has been erected, the Polyacanthocephala. The few known members of this group have been little studied. Fishes and crocodiles were found to be parasitized.

Important Species

Table 1.

Life Cycles

Figures 4 and 5.

Acanthocephala, Fig. 2 Life cycle of common acanthocephalan species. **A** ▶ *Macracanthorhynchus hirudinaceus*; **B** ▶ *Polymorphus minutus*. 1 The adults live in the intestine of their final hosts, being attached by their hooked proboscis. The penetration of the intestinal wall leads to inflamed protrusions (IP) appearing along the outer side. 2 After copulation the adult females excrete eggs for several months (patent period). These eggs are passed fully embryonated (i.e., they contain the hooked ▶ acanthor larva) with the faeces of the host. 3–6 Intermediate hosts (*Gammarus* spp. or beetle larvae) become infected by

ingesting infective eggs. Inside the intestine the acanthor is released from the egg (4), enters the body cavity, and is transformed into an ▶ acanthella larva (5). The latter grows up within 60–95 days (in *M. hirudinaceus*) and is described as an infective larva (▶ Cystacanth). Infection of the final hosts occurs when they swallow infected intermediate hosts. The young worms reach sexual maturity within 60–90 days in *M. hirudinaceus* (after 20 days in *Polymorphus minutus*) and start egg production (= end of prepatent period). AC, acanthor; BH, body hooks; IP, inflamed protrusion of IW; IW, intestinal wall; PH, proboscis hooks; RA, released acanthor

Acanthocephala, Fig. 3 Life cycle of two common acanthocephalan species parasitizing fish. **A** ► *Neoechinorhynchus rutili*; **B** ► *Acanthocephalus anguillae*. 1 Adults are attached to the intestinal wall of their final hosts, trout (A) or chub and other fish (B). 2 Fully embryonated eggs are passed with host's faeces. 3–6 Intermediate hosts (A ostracod crustaceans, B *Asellus aquaticus*) are infected by uptake of eggs. Inside their intestine the acanthor larva (4) is released from its eggshell, enters the body cavity and becomes transformed into the acanthella larva (5). This stage differentiates to the infective larva without ► encystation in about 30–60 days (6)

depending on outer conditions. Final hosts are infected by swallowing intermediate hosts. In *A. anguillae* a ► paratenic host may also become involved. When bleaks and some other fish ingest intermediate hosts (*Asellus aquaticus*), the infective larva enters the fish viscera, but there is no further development, but quick degeneration. *Neoechinorhynchus rutili* and *A. anguillae* reach sexual maturity in about 20–30 or 40–60 days, respectively (prepatent period). Adults live only for about 2–3 months (patent period). AC, acanthor; IP, inflamed protrusion of IW; IW, intestinal wall; LM, ► lemniscus; PH, proboscis hooks

Acanthocephala, Fig. 4 (a–c) Schematic drawings of the acanthocephalan praesoma and the corresponding mode of attachment. *Black area*: tissue necrosis, *hatched area*: tissue neoplasia. **(a)** Acanthocephalan with a short neck, and lemnisci branching away from the posterior end of the praesomal tegument. A deep proboscis cavity is formed. Necrotic host tissue (*black area*) can be found all around the parasite's proboscis. **(b)** Perforating acanthocephalan with a long neck, and lemnisci branching away from the praesomal tegument at the mid-neck. In the chronic mature stage of infection the proboscis becomes deeply embedded in the intestinal wall and is usually kept

fully evaginated. Necrotic host tissue is mainly confined to the proximity of the proboscis. Tissue neoplasia is pronounced also proliferating into the peritoneal cavity. **(c)** Perforating acanthocephalan with a long neck, a bulbus and lemnisci branching away from the praesomal tegument at the mid-neck. In the chronic (mature) stage of infection the parasite is “doweled” in the intestinal wall with the bulbus. The proboscis is usually kept fully evaginated. Necrosis is mainly confined to the tissue close to those parts of the worm that project into or border the peritoneal cavity. Tissue neoplasia especially in the peritoneal cavity is conspicuous

Attachment

Concerning the attachment to the host's intestinal wall, two groups can be distinguished: perforating and non-perforating acanthocephalans.

Non-perforating Acanthocephalans

Generally, acanthocephalans that have a short neck do not penetrate deeply into the host's intestinal wall with their praesoma, but display some mode of shallow attachment, i.e., they do not create lesions reaching as deep as into the muscular layers of the intestinal wall (Figs. 2, 6, and 7, ► [Acanthocephalan Infections](#), Fig. 8). Accordingly, often even the posterior half of the proboscis does not become surrounded by host tissue (Fig. 6). Layers of connective tissue within the hosts' intestinal wall often appear to function as penetration obstacles. This might be the stratum compactum in salmonids retaining ► [Echinorhynchus truttae](#) in superficial positions

or a collagen layer interiadly lining the intestinal mucosa of perch (*Perca fluviatilis*) affecting the mode of attachment of ► [Acanthocephalus lucii](#) (Fig. 6). On the other hand, the tipped proboscis hooks seem to use the collagen layers as suitable substrates of anchorage (Fig. 7). In Fig. 7 a necrotic tissue with a slight infiltration of granulocytes and haemorrhagic involvement, typical of the attachment site of *Acanthocephalus lucii* and other non-perforating species, is shown (Fig. 2). When non-perforating species were experimentally inoculated into small specimens of fish not comprising penetration obstacles in their gut wall, three non-perforating species did not try or succeed in perforating either. And accordingly such species usually cannot be found *in toto* in extraintestinal locations like perforating species. *Paratenuisentis ambiguus* and *P. lucii*, both non-perforators, do not possess collagenolytic ► [proteinases](#) useful in chemical support of penetration activity. So paratenic hosts do not occur in the life

Acanthocephala, Fig. 5 Light micrograph of a longitudinally sectioned (paraffin section) anterior body of *Acanthocephalus lucii* attached to the intestinal wall of a river perch (*Perca fluviatilis*). Only the intestinal mucosa has been ruptured. A thin layer of collagen fibres (arrow) interlacing this epithelium was not perforated. Also note the proboscis cavity at the anterior tip of the worm showing the normal condition of the proboscis of a non-perforating species. $\times 20$

cycles of non-perforating acanthocephalans, but postcyclic transmission of intrainestinal worms like *Neoechinorhynchus rutili* in sticklebacks to predatory brown trout seems to be very common.

Such species either continuously or occasionally change their point of attachment, exposing them to the posteriadly directed intestinal peristalsis. In infrapopulations of *E. truttae* in brown trout all specimens have arrived at the posterior end of the small intestine by the time the worms have matured. As has been shown for *N. cylindratus*, a species that is potentially perforating, infrapopulations with high worm densities lead to enhancement of change of the point of attachment and consequently to greater posterior shift. An interesting feature can be observed in other

Acanthocephala, Fig. 6 TEM of a transversally sectioned proboscis hook of *Acanthocephalus lucii* surrounded by necrotic and inflamed intestinal tissue of *Perca fluviatilis*. The hook: note the perforations in its ► striped layer (SL); the connective tissue of the hook does not reach into the tip sectioned here. The hook has punctually perforated the layer of subepithelial connective tissue (SC) that can be seen in Fig. 6 at a lower magnification (arrow). But the proboscis *in toto* did not perforate this layer (LA: lamina of fine amorphous material lining the mucosal epithelium). The proboscis (not seen) is either in front or behind the plane of the section. $\times 2,000$

neoechinorhynchids. Although they occupy superficial positions, they do not seem to migrate or become shifted after an initial period of establishment, due to a firm capsule of collagen fibres enclosing their small, roundish proboscis. A negative point of the proboscis remains in the intestinal wall after deattaching a worm using forceps (► [Acanthocephalan Infections](#), Fig. 5A). Not unlikely, this massive collagen formation is provoked by the excretion of proline (► [Amino Acids](#)) or other substances by the praesoma.

A typical non-perforating species is the archiacanthocephalan ► *Moniliformis moniliformis* displaying a deep proboscis cavity and shallow attachment (► [Acanthocephalan Infections](#), Fig. 8).

Acanthocephala, Fig. 7 (a–c) Micrographs showing the proboscis tip and hooks of various acanthocephalans. (a) Longitudinal semithin section of *Paratenuisentis ambiguus* that had been exposed *in vitro* to [^3H]-glyceroltrioleate for 5 min. The proboscis is fully everted, which is not the normal condition *in vivo*. Note the intense label of the “apical organ” (AO). The lipid that has been taken up by the hooks and the surrounding tegument (PT) seems to be transported along the outer membrane and the basal membrane (BM) of the tegument; CH, connective

tissue of a hook; PR, proboscis retractor muscle. $\times 3,500$. (b) SEM of the tipped hooks at the anterior proboscis of *Acanthocephalus anguillae*. $\times 1,600$. (c) Longitudinal semithin section of a proboscis hook of *A. anguillae* that has been exposed to [^3H]-labeled lipids. Note the labelled tegument of the hook underneath its striped layer. The proboscis tegument (PT) has already absorbed huge quantities of the lipid. $\times 3,000$. CH, connective

Perforating Acanthocephalans

Many Acanthocephalans possess a long neck which may comprise a bulbus such as the *Pomphorhynchus* spp. (Palaeacanthocephala) with an inflated neck region (praesoma) (Fig. 1).

In the eoacanthocephalan *Eocollis arcanus* it is the anterior part of the metasoma which forms a bulb. In both cases the bulb functions as a dowel enabling the worm to occupy a permanent point of attachment at a specific site. The deep and quick

perforation of the intestinal wall may be supported by a proteolytic enzyme as shown for *Pomphorhynchus laevis* which excretes a trypsin-like proteinase into the culture medium. It has a collagenolytic activity and the molecular mass differs slightly among infectious larvae and adult worms removed from fish. The long-necked species *A. anguillae* does not display such abilities in lysing collagen and accordingly the collagenic stratum compactum of salmonid fishes retains most worms in rather superficial connections with the intestinal wall. In experimental infections in adult rainbow trout the worms take about 60 days to perforate the stratum compactum, in juveniles of the same salmonid host it occurs around 20–30 d.p.i. In the long run, only those worms which succeed in penetrating seem to survive for several months in this host, while the others probably do not have the potential to withstand the intestinal drift. As shown for *P. laevis*, typical perforating species do not change their site of attachment and thus do not become backwards shifted. In natural populations of fish hosts, species like *P. laevis*, *Eocollis arcanus*, or *A. anguillae* are not only found in positions with a praesoma deeply inbedded inside the intestinal wall, but also partly lying *in toto* inside the peritoneal cavity or viscera, especially in small specimens or species. Obviously, in such hosts the intestinal wall or the collagen layers within it are not strong enough to withstand the worms' penetrating activity. In juveniles of goldfish experimentally infected with *A. anguillae*, the first worms started projecting into the peritoneal cavity with parts of their praesoma up from about 10 d.p.i., worms of about 20–30 d.p.i. were mostly found in various positions like lying with parts of their bodies inside one intestinal loop and projecting into another with the proboscis or anterior body (► [Acanthocephalan Infections](#), Fig. 5). In contrast, at 50 d.p.i. all worms recovered had taken intraperitoneal positions and most of them were already degenerating. Due to this quick death of the worms in extraintestinal positions, one may conclude that they did not leave the intestine "on purpose" but slipped into the peritoneal cavity *in toto* by lack of penetration obstacles or other features. Thus, the small fishes that became infected

in these experiments should not be called ► [paratenic hosts](#). However, true paratenic hosts exist in the life cycles of certain perforating acanthocephalans. *Oncicola pomatostomi*, for instance, is parasitic in the intestine of Felidae and Canidae in Southeast Asia and Australia while it has been found under the skin of 19 species of passerine birds where it probably has a certain longevity making the birds true paratenic hosts.

Often *Macracanthorhynchus hirudinaceus* occupies extraintestinal positions in humans. The migration of this perforating acanthocephalan through the gut wall is very painful. Such infected humans with an intraperitoneally located worm might be named accidental hosts since they do not play a role in the transmission of the acanthocephalan.

Among perforating species a proboscis cavity is formed mainly during the early phase in the final host when the worm has not yet penetrated, later on, the cavity's depth and frequency of invagination are progressively reduced (► [Acanthocephalan Infections](#), Fig. 5).

Food Uptake

In non-perforating acanthocephalans the proboscis itself is usually kept in a more or less invaginated condition creating a deep proboscis cavity (Fig. 2a) which obviously functions as a funnel collecting remnants of cells and nutrients leaking into the lesion that has been created by the worm. In eo- and palaeacanthocephalans, especially lipid substances such as triacylglycerols are highly abundant as storage lipids in the intestinal wall of fish, ducks, or seals serving as final host. As shown in Fig. 8 lipid matter as well as, for instance, peptides deriving from the granules of eosinophilic granulocytes contribute to the efflux from the necrotic tissue. However, autoradiographic studies by Taraschewski and Mackenstedt with two species of eoacanthocephalans and four palaeacanthocephalans (two non-perforating and two perforating species) show that predominantly lipid substances are absorbed at the worms' praesoma (Figs. 9 and 10). The "apical organ" of

Acanthocephala, Fig. 8 Longitudinally cut semithin section of the anterior body of an *Acanthocephalus lucii* that had been *in vitro* exposed to [3 H]-vitamin A for 15 min. Note the intense label of the anterior half of the proboscis tegument which lines the proboscis cavity normally formed. Behind the septum between the praesomal and the metasomal tegument (black arrows) almost no absorbance of the substance offered has taken place. However, it appears that the accidentally formed “shoulder” of the metasoma that obviously was in contact with the praesoma during the exposure has attained some label in its tegument (white arrows), suggesting that this part of the metasoma took advantage of enzymatic activity prevailing at the praesomal surface. $\times 60$

eoacanthocephalans, a structure not yet well understood at the tip of the proboscis, i.e., at the bottom of the proboscis cavity (Fig. 9), and the tegument of the anterior half of the proboscis (Fig. 10) play the most active role in lipid uptake. Interestingly, the proboscis hooks, too, can be considered organs well adapted to the task of lipid uptake (Figs. 9 and 10). In accordance with their tapered and tipped construction (Fig. 9b) the hooks are in reach of lipid deposits which are not (yet) in contact with the surface of the praesoma. Behind the septum between praesomal and metasomal tegument the uptake of a triacylglycerol as well as of ► vitamin A was

Acanthocephala, Fig. 9 Autoradiographically treated longitudinal section of the anterior body of a female *Echinorhynchus truttae* that was exposed to [3 H]-lysine for 8 min. Note the less intense label of the presomal tegument (PT) compared to the metasomal tegument. $\times 100$. SE, septum between the praesomal and the metasomal tegument (compare Fig. 13b); LA, tegumental lacunar system; LE, lemniscus; N, nucleus

very low in *in vitro* trials. However, if “shoulders” of the metasoma were in contact with the praesomal surface during the exposition of a worm to the labelled nutrient, the shoulders too revealed a markable label (Fig. 10), suggesting that enzymes localized at the praesomal surface were involved. Uptake of amino acids as well as monosaccharides also occurs at the surface of the praesoma (Fig. 11), but the metasomal tegument seems to be the major absorptive surface for these substances.

Concerning the uptake of nutrients by adult perforating species, the mechanisms do not basically deviate from those described for non-perforating species. Since the whole praesoma is deeply embedded in the gut wall, a funnel for substances leaking into intestinal lumen is not very large. Intra-intestinally attached worms that have a bulbus can be easily recognized at the

Acanthocephala, Fig. 10 Semithin section of the proboscis of a specimen of *Neoechinorhynchus rutili* attached to the gut wall of a naturally infected juvenile rainbow trout. Note the conspicuous quantities of lipid (LI) accumulating at the worm's proboscis. They seem to derive from the surrounding necrotic tissue. Also, fused granules from degranulated eosinophilic granulocytes (arrow) are abundant, fusing with the lipid drops. In such a methylene-blue-stained section the lipid attains a greenish-golden colour while the fused granules are a deep blue. Thus both substances can be distinguished well. $\times 100$. AO, apical organ

Acanthocephala, Fig. 11 Transmission electron micrograph of a section through the distal part of the praesomal tegument of *Acanthocephalus anguillae* (in a rainbow trout, 90 d.p.i.). Note the thick lipoid surface coat (SC) between the tegument and the necrotic tissue (NT) at the point of attachment, also the fused crypts of the outer membrane (FC) with supporting microfibrils in it and the underlying feltwork layer (FL). A section with little osmiophilic content of the fused crypts was chosen in order to show the microfibrils in it. $\times 25,000$

gut's exterior side (► [Acanthocephalan Infections](#), Fig. 6) but also in species without a bulb, like *M. hirudinaceus*, a fibrous whitish ► [nodule](#) with reddened annulation around it can be seen.

Integument

The tegument of acanthocephalans is a ► [syncytium](#) of up to 2 mm in thickness (*M. hirudinaceus*). It either contains numerous small nuclei (Fig. 12c) or specific numbers of giant nuclei in eacanthocephalans (Table 1). The nuclei of the tegument of the metasoma (trunk) are not immersed below the tegument

(Fig. 12c). In the praesoma (proboscis and neck), however, the nuclei are harboured by the lemnisci; sack-shaped outgrowths of the praesomal tegument projecting into the body cavity (Fig. 3). The tegument is supported by underlying fibres of connective tissue, partly identified as collagen, of equal thickness in all parts of the body, and by cords of circular (only in the metasoma) muscles and longitudinal muscles (in both parts of the body; Fig. 12c). These components together build up the body wall (Fig. 12c). The tegument shows a typical stratification and a differentiation related to the praesoma-metasoma organization of the acanthocephalan body.

Acanthocephala, Fig. 12 (a, b) TEMs of the distal part of the adult acanthocephalans' tegument. (a) Section through the metasomal tegument of *Acanthocephalus lucii*. Note the striped layer (SL) functioning as a cuticle. It is perforated by densely set crypts of the outer membrane (CM). PO, pore of a crypt; GL, glycocalyx (which is thin on the specimen shown here). (b) Section through the area around the septum (SE) separating the praesomal tegument (PS) (which is folded in this worm shown *in vivo*) from the metasomal tegument (ME) of *Acanthocephalus anguillae*. Note the abundance of lipid (LI) in the praesoma and the osmiophilic film (OF) obviously shed from the praesomal surface into the thick, apparently liquid surface coat of the praesoma. $\times 28,000$

Metasoma

- The syncytial tegument of the Acanthocephala is delimited by a plasma membrane carrying a filamentous ► [surface coat](#) (Fig. 13a) which has a similar appearance in all systematic groups of these worms regarding the surface of the metasoma (Fig. 13, Table 1). This ► [glycocalyx](#) also covers the pores (openings of the outer membrane's crypts) of the

tegument. It may reach a thickness of up to 1 μm or more and obviously proteoglycans are present in it. Infective larvae inside the intermediate host's hemocoel carry the most conspicuous surface coat. The plasma membrane itself forms densely set crypts projecting into the outer part of the tegument. Their greater density in the metasoma compared to the praesoma might have to do with the heavy competition pressure between the trunk surface being located inside the gut lumen, and the host's intestinal mucosa for the absorbance of nutrients. The crypts have been calculated to increase the worm's "outer" surface 20- to 80-fold. The crypts have slender necks with electron-dense annulations underneath their outer openings (seen as pores by SEM) and they form branches directly underneath the pores or further inside the tegument. The crypts are considered extracytoplasmic digestive organelles which under the influence of surface hydrolytic enzymes maximize the opportunities of food absorption by these gutless worms. So it might be a point of debate whether the membrane limiting the lumen of the crypts really is an "outer" surface (Fig. 13).

- Interiably, the outer membrane is supported by an electron-dense layer of about 5 μm in thickness. Due to perforations of this "► [cuticle](#)" by the crypts, this layer obviously having stabilizing functions is seen as a striped layer in TEM micrographs (Fig. 13). Usually the longitudinal extension of the membrane-crypts considerably exceeds the diameter of the striped layer, forming a spongy belt rich in pinocytotic activity (Fig. 13). This layer is considered a "► [vesicular layer](#)" by a few authors.
- The feltwork layer adjoining underneath again seems to contribute to the skeletal task of the tegument but its diameter is about five times larger than that of the striped layer (► [Acanthella](#), Fig. 1, showing this feature in the praesoma). It is characterized by fibres displaying no particular order, and normally it contains large amounts of glycogen. Metasomal spines, present in many palae- and eoacanthocephalans (Table 1), have been described as outgrowths of the feltwork layer

A

Acanthocephala, Fig. 13 (a–c) TEMs of sections through the proboscis tegument and hooks of the eoaacanthocephalan *Paratenuisentis ambiguus*. (a) The curved hook which is retracted in this micrograph is sectioned twice, at its connection with the subtegumental connective tissue (CH, connective tissue of the hook) and at its tipped outer portion. Note the lipoid substance (LI) being excreted through the pores in the hook, which (or a similar substance) is also abundant in the surrounding tegument; SC, connective tissue of the presomal tegument; ER, rough endoplasmic reticulum. $\times 10,000$. (b) Cross section through a retracted hook and neighbouring proboscis tegument. The section has been treated according to the

electron microscopical PAS-staining method by Thiéry. Note the mucus-like carbohydrates inside (CM, crypt of the hook's outer membrane) and outside the hook (arrow). $\times 56,000$. (c) TEM of the basal part (radial layer) of the metasomal tegument of an adult *Acanthocephalus anguillae*. Note the radially arranged fibres (RF) with fibrous, electron-dense material (FM) attached to them, the labyrinthine basal membrane (LB) and the cords of subtegumental musculature (CM, circular muscle; LM, longitudinal muscle) consisting of an outer myogenic portion (MP) and an inner non-contractile portion (CP); BL, basal lamina; LD, lipid drop; N, nucleus; NU, nucleolus; SC, subtegumental connective tissue. $\times 50,000$

and are thus invested by a thin cover of a somewhat condensed striped layer. These trunk spines, often ornamenting a wider part of the ventral surface than of the dorsal

side, are thought to act as additional holdfast organs.

- The more proximal radial layer (Fig. 12c) occupies more than 70 % of the tegumental

diameter. This layer is considered to be the main metabolic centre of the acanthocephalan body. During the (allometric) growth of the worms it is mainly the increase in diameter of the radial layer which leads to a thicker tegument. This layer is characterized by radially arranged fibres connected to the basal membrane. Electron-dense matter accumulates around the spokes (Fig. 12c). This layer harbours the tegumental nuclei (Fig. 12c) and the major canals of the lacunar system (Fig. 14c). The lumen of this system is poor in organelles and electron-dense matter (Fig. 14c) and in autoradiographic trials it takes up and/or retains less nutrients than the surrounding ► [cytoplasm](#). Also its glycogen content is low in contrast to the true radial layer, which usually stores plenty of this carbohydrate. Apparently contractions of the subtegumental musculature (Fig. 12c) act as the motive force for fluid flow inside the lacunas. However, it remains unclear whether these caverns fulfil functions of a circulatory system.

- The basal membrane, interiadly bounding the tegumental syncytium, shows a typical labyrinthine structure. Along its distal surface it is supported by amorphous matter, whereas a thin lamina of a fine matrix lines the proximal side of the membrane (Fig. 12c).

Praesoma

The tegument of the praesoma is separated from that of the trunk by a septum composed of fibres and adherent amorphous matter (Fig. 13b). So even the lacunar cavities are part of two different systems, which might make sense considering the assumed involvement of hydrostatic pressures in the protrusion, invagination, and retraction of the proboscis or the entire praesoma. Within the praesoma mainly the neck possesses lacunar cavities. The praesomal tegument reveals major differences compared to that of the metasoma and these features become more prominent towards the anterior part of the proboscis. Generally, the praesomal tegument contains more amorphous, electron-dense matter, more ► [mitochondria](#), and rough and smooth endoplasmic reticulum (Fig. 12a) as well as lipid (especially in eo- and

palaeacanthocephalans, Figs. 12a and 15) than the metasomal tegument. Interestingly, a submersion of the tegumental nuclei only occurs in the praesoma. The lemnisci harbouring the nuclei (Fig. 3) do not show a specific stratification like the tegument they branch away from. They too contain lacunar spaces, and are very rich in lipid.

The surface coat of the praesomal tegument reveals systematics-related specificities (Fig. 15) and shows interesting links with the host–parasite interactions (► [Acanthocephalan Infections](#)). The fine structure and obviously also the chemical composition of the surface coat vary among the classes. Regarding archiacanthocephalans the optical impression of the praesomal glycocalyx resembles that of the metasoma, although it is more coarsely structured and more osmiophilic than the latter. Shedding of the surface coat frequently or often occurs and seems to follow a complexation of host's anti-parasitic enzymes or antibodies with the surface coat (► [Acanthocephalan Infections](#), Fig. 5A). Eoacanthocephalans and palaeacanthocephalans reveal a lipid, non-fuzzy surface coat which may reach a thickness of several microns (Fig. 16) and shows a matrix which suggests a liquid or semiliquid condition. In addition to lipid, mucus-like carbohydrates are also present in it. Often osmiophilic films, perhaps representing a “glycocalyx,” can be seen in it, and it is rather likely that these films are shed into the voluminous coat once the outer membrane has become loaded with anti-parasitic peptides of the host's defense system (Fig. 13b). Unfortunately, the chemical properties of the acanthocephalan ► [surface coat](#) have not been extensively studied to date.

The (pores of the) praesomal crypts are less densely set and the striped layer measures half or less in diameter than the trunk surface. In Palaeacanthocephala the single crypts are fused underneath the striped layer, forming large caverns with stabilizing fibres in them (Fig. 15b). The other systematic groups have retained their individual crypts (Fig. 15a, c). Generally, the strata of the tegument as described from the trunk cannot be well distinguished: due to the abundance of fibres they often all together appear like a feltwork

Acanthocephala, Fig. 14 (a, b) Micrographs of acanthocephalan muscles of *Paratenuisentis ambiguus* showing their bi-component construction comprising an outer myogenic belt (MP) and an enclosed cytoplasmic portion (CP). (a) Longitudinally ultrathin-sectioned subtegumental muscle of an infectious larva. The section has been treated according to the electron microscopical PAS method of Thiéry in a mode to visualize glycogen. Note the intense Thiéry label in the core of the muscle; LD, lipid drop; SC, subtegumental connective tissue; SE, septum. $\times 260$. (b) Transversally semithin sectioned body cavity of an adult worm that was exposed to ^3H -glucose and then autoradiographically treated. The intense label in the cytoplasmic portion of the receptacle retractor muscles (RR) seems to be due to glucose-metabolites (probably

mainly glycogen) incorporated in these muscles; CK, knobs on the muscle's surface also showing the bi-portion structure; E, egg; LS, ligament strand; OB, ovarian ball; SL, subtegumental longitudinal muscle. $\times 300$. (c, d) Semithin sections of the praesoma (and partly the metasoma: c) of adult acanthocephalans. (c) Longitudinal section showing the cytoplasmic "finger" (CP) of the (inner) receptacle wall projecting into the proboscis. Also note the lacunar system (LS) inside the metasomal tegument (MT); SE, septum between praesomal and metasomal tegument. $\times 30$. (d) Transverse section through the receptacle wall musculature (IW, inner wall; OW, outer wall) of *Acanthocephalus lucii*; note the tubular structure of the proboscis retractor musculature with its cytoplasmic cores (CP) of low density. $\times 150$.

Acanthocephala, Fig. 15 (a–c) (a) Schematic drawing of an eoacanthocephalan proboscis hook and surrounding tegument. Note the tegumental cover of the hook's connective tissue (*CH*), and the crypts of the outer membrane (*CM*) entangling with "crypts" of the tegument's basal membrane externally lining the connective tissue of the hook. These crypts perforate a layer of amorphous matter (*AM*) covering the connective tissue of the hook's tegument. *LC*, lipid coat on the hooks and on the tegument; *PM*, finger-shaped protuberance of the subtegumental musculature; *SC*, subtegumental connective tissue. (b) Schematic drawing of a palaeacanthocephalan proboscis hook and surrounding tegument. Note the tegumental cover of the hook's connective tissue (*CH*), the lipid coat (*LC*) on the tegument and the hook, the fused crypts

of the outer membrane (*FC*) supported by fibres, and the fused crypts of the basal labyrinth (*FB*) which possibly are continuous with the latter fused crypts. *PM*, finger-shaped protuberance of the subtegumental musculature; *SC*, subtegumental connective tissue. (c) Schematic drawing of an archiacanthocephalan proboscis hook and surrounding tegument. Note that the connective tissue of the hook (*CH*) has no tegumental cover and is invested only by a lipid coat (*LC*) which is discharged by the tegument into the pouch surrounding the hook. The proboscis tegument carries a fuzzy ▶ [glycocalyx](#) (*GL*), and the crypts of the outer membrane (*CM*) are not fused. *PM*, finger-shaped protuberance of the tegumental musculature; *SC*, subtegumental connective tissue

layer. The metasomal labyrinthine structure of the basal membrane is considerably reduced and instead its coating with amorphous material is more pronounced.

Proboscis Hooks

Irrespective of the systematic affiliation of the worms the hooks (Figs. 9b, 12a, b, and 15) possess a central cone of connective tissue which partly has been demonstrated to contain collagen and/or ▶ [chitin](#). This major part of the hook arises from the subtegumental connective tissue. In its proximal part it encircles a finger-like projection of the subtegumental longitudinal musculature (Fig. 15). But this musculature tie is not present in all hooks of all species, implying that not all hooks can be individually retracted.

In eo- and palaeacanthocephalans the fibrous core of the hooks carries a condensed tegumental cover making these holdfast organs pointed (Figs. 12 and 15a, b). The striped layer does not markedly differ between eo- and palaeacanthocephalans but in eoacanthocephalans the crypts are not fused but entangle with finger-form protrusions of the tegument's basal membrane inside the hooks (Fig. 15a). In both of these subclasses the tipped hooks are capable of discharging lipid substances through their pores (Fig. 12a). Mucus-like carbohydrates also contribute to the excreted matter (Fig. 12b) and, rather likely, enzymes are also contained in it which thus far can only be hypothesized. The grease-like surface coat of the hooks may be very voluminous (Fig. 15). Amazingly, however, the hooks are also capable of

Acanthocephala, Fig. 16 (a) DR of a female acanthocephalan (*Paratenuisentis ambiguus*, Eoacanthocephala) with emphasis on the sexual organs (most muscles omitted). It has been reduced in size (length) compared with the male worm. The ventral ligament sac leading into the uterine bell is specific to eoacanthocephalans. Note the lack of genital ganglia (GA) in the female worm. For the inscriptions of the non-sexual organs see (b). Eggs and floating ovaries inside the ligament sacs are not shown (Fig. 18a). (b) DR of a male acanthocephalan (*Paratenuisentis ambiguus*, Eoacanthocephala) with

emphasis on the sexual organs. Most muscles are omitted. The single polynucleate cement gland and the presence of a cement reservoir and a seminal vesicle are specific to eoacanthocephalans. AS, apical sensory organ; BC, bursa copulatrix (evaginated); CG, cerebral ganglion; DL, “dorsal” ligament sac; ES, egg-sorting apparatus; G, genital opening; GS, Saeftigen’s pouch; HO, testes; LE, lemnisk; M, muscle; N, giant nucleus; PR, proboscis with hooks (evaginated); SB, seminal vesicle; SP, sphincter; TE, tegument; UG, uterine bell; UT, uterus; VL, “ventral” ligament sac; ZD, cement gland; ZR, cement reservoir

absorbing nutrients from the host tissue surrounding them.

In archiacanthocephalans the hooks do not bear a tegumental vestment and the naked cone of the connective tissue, thus piercing the tegument, is less pointed than the hooks of the

two other systematic groups (Fig. 15c). Obviously, the hooks attain their slippery surface cover by dipping into a pit encircling them; this annular cleft filled with a highly osmiophilic lipid paste deriving from the surrounding tegument (Fig. 15c).

Uniformly in all systematic groups of the Acanthocephala, the close tegumental surrounding of the hooks is rich in lipid droplets, mitochondria, and rough (Fig. 12a) as well as smooth endoplasmic reticulum, indicating elevated metabolic activity.

Proboscis Cavity

Contrary to the way in which acanthocephalans are usually shown in drawings made from dead worms (Fig. 3), *in vivo* and *in situ* the acanthocephalan proboscis is normally kept in a semi-invaginated position, especially among species with superficial attachment (Fig. 2). Thus a proboscis exhibiting a more or less deep anterior cavity resembling a mouth opening should be part of our idea of these gutless worms. Among eo- and palaeacanthocephalans inside the proboscis cavity the tegumental surface including the hooks appears as a labyrinth with remnants of host cells and tissue between its curves and with grease occupying all external niches of the labyrinth at its bottom plane.

In Archiacanthocephala the proboscis cavity is not filled with grease in its inner part and the labyrinth is lined by the fuzzy ► [glycocalyx](#) described under ► [praesoma](#).

Musculature

Relatively few investigations have dealt with the fine structure of the acanthocephalan musculature. Some muscles, such as the receptacle retractor muscles, appear obliquely striated, e.g., fibres are connected to Z-line-like structures.

The basic feature of the acanthocephalan musculature is its 2-component structure composed of an outer myogenic, contractile belt and a cytoplasmic core enclosed by it (Figs. 12c and 14). The interior part seems to have a function in energy storage.

Usually glycogen is very abundant in it (Fig. 14a) and in autoradiographic experiments with labelled glucose, the glucose, or more likely metabolites of it like glycogen, accumulates in the cytoplasmic core (Fig. 14b). The cords of subtegumental musculature follow this

bi-component composition (Fig. 12c), as do the retractor muscles (Fig. 14b–d). In addition the receptacle retractor muscles also carry small knobs on their surface which have non-contractile cores (Fig. 14b). In all these muscles the central non-contractile portion may contain plenty of organelles, mainly mitochondria, or may be rather electron-lucent, suggesting a higher fluidity than the latter cytoplasm. Inside the proboscis retractor musculature a low viscosity core should enable a quick directional shift of the enclosed cytoplasm when the proboscis cavity is formed or discontinued. An interesting differentiation is shown by the proboscis receptacle musculature enclosing and thus forming the hollow into which the proboscis can be retracted. In palaeacanthocephalans it consists of a double wall which has almost no non-contractile portion (Fig. 14d). In eoacanthocephalans it is considered single-walled but the “receptacle protrusor musculature” exteriorly surrounding the receptacle without being firmly connected to it probably represents the outer wall of the receptacle. It reveals the described 2-portion structure. The inner wall basically consists of a firm, contractile wall but on its dorsal inner side a conspicuous sack-shaped cytoplasmic outgrowth with a very narrow contractile outer cover projects into the posterior half of the proboscis (Fig. 14c). The cytoplasmic finger seems to function as the major glycogen deposit of the praesoma. In archiacanthocephalans the inner wall consists of plane myogenic tissue whereas the outer wall is formed by spirally arranged single muscle cords with non-contractile cores. Due to this spiral arrangement the retraction and protrusion of the praesoma (not only the proboscis can be invaginated) are performed in a torsion-like, screwing fashion.

Excretory System

Excretory products of most acanthocephalans seem to be released exclusively through the body wall, but it is not known whether this takes place through the whole tegument or through special regions. In addition, oligacanthorhynchids

and probably other archiacanthocephalans have protonephridia. Their efferent canals either lead into the vas deferens (male) or into the uterine bell (female). Two types of protonephridia are known:

- Dendric type: numerous flame cells drain into branched canals which lead into a central canal;
- Saccular type: the flame cells drain into an encapsulated bowl and a subsequent central canal.

Excretory products of acanthocephalans seem to be similar to other helminths, containing lactate, succinate, etc. Ethanol, however, has been described as the main excretory product of ► *Moniliformis moniliformis*. There is still controversy over whether acanthocephalans are osmoconformers or not, but most species seem to have little osmoregulatory ability.

Reproduction

Acanthocephalan reproduction as well as the fine structure and genesis of the ► oocytes and spermatocytes show some unique features.

Reproductive Organs

Acanthocephalans are ► dioecious. Male worms are usually smaller than females, and in addition ► sexual dimorphism may affect other features such as trunk spination. Only males have a pair of genital ganglia (and a bursal ganglion, so far only described for *M. moniliformis*), whereas both sexes have a cerebral ganglion. Sensory papillae of the genital region are confined to males. And indeed only males seem to be active in finding a sexual mate and copulation. In female worms the sexual organs lie within two ligament sacs (Fig. 3a) which rupture in palaeacanthocephalans and some eoacanthocephalans. The male sexual organs are located within only one ligament sac (Fig. 3b).

The male gonads and accessory organs are enclosed by the dorsal ligament sac (the ventral sac does not persist in males), and further posteriadly, by the muscular genital sheath

(Fig. 3b). The organs are attached to the ligament strand which keeps them in position. Males normally have two testes, but ► monorchidism is rather frequent. A seminal vesicle may be present (Eoacanthocephala). The vasa efferentia fuse to form a vas deferens, which fuses with one or several ducts of the cement gland(s) to form a genital canal. Cement glands are significant accessory organs (1–8 in number), and eoacanthocephalans have a separate cement reservoir. The cement locks the female vagina after copulation until the first embryonated eggs are released, and forms typical copulatory caps on the posterior tips of inseminated females. But dominant males may also use this secretion to prevent inferior male competitors from fertilizing females of the respective intrapopulation. If protonephridia are present, the genital canal is joined by the (ciliated) excretory canal. The genital (or urogenital) canal leads into the ► bursa copulatrix (Fig. 3b). The muscular terminal part of the genital canal inside the bursa is considered a penis. Additional accessory organs are the Saeftigen's pouch and a few glandular structures associated with the bursa that are not yet well known. The fluid-filled muscular Saeftigen's pouch is connected with the lacunar system of the bursa tegument. By its contraction it regulates the hydrostatic pressure of the bursa and thus its protrusion or invagination (Fig. 3b).

The female reproductive system consists of two major tubes:

- The ligament sacs (or the pseudocoel if the sacs are ruptured) that contain the floating ovaries (ovarian balls).
- An efferent duct system including a complex egg-sorting apparatus which is unique among helminths.

The two ligament sacs are interconnected at their anterior end. Posteriad, one sac leads into the uterine bell while the other is connected to a lateral opening of the subsequent apparatus (Fig. 3a).

The muscular efferent duct consists of the uterine bell, the egg-sorting apparatus, the uterus, and the vagina which is enclosed by one or two genital sphincters (Fig. 3a). Eggs from the dorsal

(Archiacanthocephala) or ventral (Eoacanthocephala) ligament sac are “sucked” into the funnel-shaped bell which leads into a narrow duct. The subsequent egg-sorting apparatus of *M. moniliformis* consists of two lateral pockets, two dorsal median cells, two anterior ventral median cells, two posterior ventral median cells, and two lappet cells. It ensures that normally only embryonated eggs are found in the host’s faeces. By a complex interaction between the muscular activity of the bell wall and the cells and pockets of the apparatus, only embryonated eggs are allowed to enter the uterus, while immature ones are forced back into the ventral (Archiacanthocephala) or dorsal (Eoacanthocephala) ligament sac. The egg-sorting mechanism is not fully understood. The uterus is surrounded by layers of muscles and fibrous material. The vagina is a narrow duct which connects the uterus with the gonopore (Fig. 3a) and was found to carry glandular appendages in some species. The gonopore of a few species is surrounded by genital spines, and after insemination is generally blocked by a copulatory cap imposed on it by the male until eggs are released.

Gametogenesis

Acanthocephalan reproduction as well as the fine structure and genesis of the oocytes and spermatoocytes show some unique features. Acanthocephalan ► **spermatozoa** are filiform (Fig. 17) and consist of a nucleocytoplasmic spermatozoan body rich in glycogen, and a flagellum. They measure 20–80 µm in length depending on the species, and obviously do not possess mitochondria or acrosomes. They contain a longitudinal chromatin strand (which is not membrane bound), two lateral rows of “dense inclusions” of unknown function and a ► **centriole** which gives rise to the flagellum. The ► **axoneme** of the free flagellum consists of microtubules which in most species are arranged in a $(9 \times 2) + 2$ pattern, but also either one or three central tubuli have been found even within one species. The microtubules may show typical dynein arms, but the pattern is

not consistent (Fig. 17). Among the phases of spermatogenesis the spermiogenesis is best described. It is characterized by several events:

- The centriole of the flagellum migrates from the posterior to the anterior region of the spermatid while the spermatids are still connected in clusters (Fig. 17b) by cytophoral stalks. The flagellum then extends slightly posteriorly (while the nucleus becomes elongated) and finally it extends greatly anteriorly (Fig. 17c). Thus, as a result of this extension the spermatozoan body becomes reversed in relation to the free flagellum.
- The nuclear membranes disintegrate to form the nucleocytoplasmic body (Fig. 17a, c). Only a remnant of the nuclear envelope remains.
- The mitochondria disappear from the spermatozoan body.
- The spermatozoan body detaches from the spermatid’s residual body containing the mitochondria.

Several species of acanthocephalans have been found to be precocious, e.g., mature spermatozoa have been found in male larvae.

Mature oocytes are spherical cells that lie below the surface of the free-floating ovaries (ovarian balls) and show typical electron-dense inclusions (Fig. 18a, c). The floating ovaries derive from the ovarian primordium of some larval stage. Immature floating ovaries have a thick surface coat and lack microvilli-like structures of their outer membrane. Mature ones consist of two syncytia, i.e., the central oogonial syncytium and the peripheral supporting syncytium. Furthermore they contain developing oocytes which seem to derive from the oogonial syncytium. The superficial supporting syncytium reveals microvilli-like outgrowths of its surface which absorb nutrients from the body cavity, as can be demonstrated by autoradiographic experiments. Fertilized ovaries (and unfertilized mature ovaries of a few species) apparently lose their ► **microvilli** (Fig. 18c). The actual process of oogenesis from oogonia to mature oocytes is not yet well known.

Acanthocephala, Fig. 17 (a–c) Acanthocephalan spermatozoan and spermatid morphology. (a) DR of an acanthocephalan spermatozoan. 1, 2 Transverse sections through the spermatozoan body ($\times 2$) and through the flagellum ($\times 3$). (b) Transmission electron micrograph of a cluster of spermatids of *Echinorhynchus truttae* in the process of nuclear and flagellar elongation, i.e., spermiogenesis. Note the numerous mitochondria (MI) inside the spermatids. $\times 6,840$. (c) TEM of a transverse section through spermatids (ST) and early spermatozoans (SB) of

E. truttae. Note the apparent lack of mitochondria in the spermatozoan body and the rupturing nuclear envelopes (RN) in some spermatozoans. $\times 39,900$. CL, centriole; CR, chromatin; DI, electron-dense inclusions; FE, flagellum extending from the anterior part of a spermatid posteriad; FL, flagellum; GB, Golgi body; MI, mitochondrion; MT, microtubules with dynein arms; N, nucleus; NE, nuclear envelope; NR, remnant of nuclear envelope; RN, rupturing nuclear envelope; SR, spermatozoan body; ST, spermatid; TF, terminal flagellum

Acanthocephala, Fig. 18 (a–c) Micrographs of acanthocephalan floating ovaries and fertilization of the enclosed oocytes. (a) LM. Floating ovaries (FO) are contained within the two ligament sacs which are separated by the fibrous ligament strand (LS) (*Paratenuisentis ambiguus*, Eoacanthocephala). Note the oocytes (O) lying underneath the surface syncytium (SS) of the ovaries, adhering sperms (SP), the detached zygotes (DZ), and the shell-coated developing eggs (E). $\times 260$. (b) SEM. A floating ovary from the body cavity of *Acanthocephalus anguillae* (Palaeacanthocephala) shows numerous sperm at its surface. The flagellum is visible as a slender prolongation of the spermatozoan body. Note the detaching zygotes (DZ) which already resemble the spindle shape of the mature

eggs. $\times 4,560$. (c) TEM. Sperm have penetrated the surface syncytium and the underlying oocyte (zygote?) of a floating ovary of *Neoechinorhynchus rutili*. The accumulation of “inclusions” (IN) at the oocyte’s margin seems to follow fertilization and possibly initiates the formation of the egg-shell. $\times 16,450$. CM, circular musculature; CP, cytoplasmic part of muscle; CT, connective tissue; DZ (black), detached zygote; DZ (white), detaching zygote; E, shell-coated developing egg; FO, floating ovaries; IN, inclusion; LM, longitudinal musculature; LS, ligament strand; MI, mitochondria; MP, myogenic part of muscle; N, nucleus of oocyte; NU, nucleolus of oocyte; O, oocyte; RR, receptacle retractor muscle; SP, spermatozoa; SS, surface syncytium of floating ovary; TE, worm’s tegument

Fertilization

Acanthocephalan females may become inseminated subsequently several times. But little is known about how the worms attract each other – if they do so – prior to copulation and insemination. According to observations by Richardson et al. in the palaeacanthocephalan *Leptorhynchoides thecatus*, parasitizing in green sunfish, mate finding follows a very simple pattern. Individuals of both sexes are usually positioned inside the pyloric ceca in a mode such that their posterior ends extend into the intestinal lumen within the small area from which the ceca originate. So emigration to find a mate is unnecessary (see also ► [Behavior](#)). There is still a lack of evidence about the function of the copulatory cap which locks the vagina of inseminated females during the prepatent period. Some philosophical debate has been held about the applicability of the “selfish gene theory” preventing males with inferior genes from reproduction. There are still open questions on acanthocephalan copulation and fertilization.

The following steps of fertilization have been documented: oocysts become fertilized whilst lying underneath the surface (syncytium) of an ovary. The flagellum of the sperm attaches to the surface of the ovary (Fig. 18b), which leads to an inflation of the flagellar apex. The subsequent penetration of the spermatozoan through the supporting syncytium into the oocyte (Fig. 18c) apparently initiates meiosis and the formation of polar bodies. The electron-dense inclusions of the mature oocyte move to the periphery and initiate the formation of a fertilization membrane around the ► [zygote](#). The zygote now becomes ovoid and gives rise to a fertilization gap between its surface and the supporting syncytium of the ovary.

Postzygotic Development

The first step of postzygotic development is the formation of the first larva, the ► [acanthor](#).

Females of all acanthocephalans release fully embryonated eggs. Prepatent periods of worms from homoiothermic hosts last between 22 days (*Polymorphus minutus*) and 70 days (*Macracanthorhynchus hirudinaceus*); in poikilothermic hosts development depends on the

temperature. These same two species may remain patent for a maximum of only 25 days (*P. minutus*) or for up to 10 months (*M. hirudinaceus*).

After being taken up by the intermediate host the acanthor changes its morphology and becomes an ► [Acanthella](#) – the stage between the acanthor and the larva that is infective to the final (or paratenic) host.

Acanthocephalacidal Drugs

General Information

The large to medium-sized ► [acanthocephalans](#) are thorny (spiny)-headed worms with an elongated ► [proboscis](#) armed with recurved hooks parasitizing the digestive tract of a wide range of vertebrate animals throughout the world, and occasionally found in humans. They have been placed in their own phylum since their affinities to other parasites are not well defined. The sexes are separate, males being much smaller than females. The life cycle of acanthocephalans infecting mammals involves intermediate hosts. There are a number of genera in the dung beetle family Scarabaeidae and cockroaches containing the infective stage of worm (► [Cystacanth](#), which is really a young adult) or vertebrates, which act as paratenic hosts (e.g., mice, and frogs) harboring re-encysted cystacanths. No acanthocephalans are primarily human parasites.

Two species of these worms may infrequently infect humans more often than others. One species is ► [Moniliformis moniliformis](#), which commonly parasitized rats and other **rodent hosts**, the other *Macracanthorhynchus hirudinaceus* (adults resemble *Ascaris suum*), a common parasite of pigs and wild boars, ubiquitous in areas where **pigs** are kept free. The final host (swine, occasionally man) becomes infected by ingesting either the infected grubs or the adult beetles and rarely the infected vertebrate. Infections may frequently occur in China and Indonesia and other parts of Southeast Asia, but also in most other countries of the world though *M. hirudinaceus* is absent from Western Europe. In **humans**, the adult worms,

Acanthocephalacidal Drugs, Table 1 Control and treatment of acanthocephala infections in humans and animals

Host (other information)	Parasite (other information)	Control and treatment (nonproprietary name, miscellaneous comments)
Humans acquire the parasite by ingesting beetles as food	<i>Macracanthorhynchus hirudinaceus</i> (pig), <i>Moniliformis moniliformis</i> (rodents)	Prevention can be effected by rodent control and keeping of food intended to be eaten cold in beetle-proof containers may help to prevent accidental infection; treatment is not well established; niclosamide (► Cestodocidal Drugs) has been successfully used in Nigeria, loperamid hydrochloride, an antidiarrheal agent, proved very active in <i>M. hirudinaceus</i> infected pigs (see below); in China, surgery is often practiced to remove adult worms from heavily infected patients
Pig, wild boar (other occurring in carnivores like wolf, domestic dog, badger, fox), others are <i>M. catalinum</i> , and <i>M. ingens</i> , <i>Oncicola canis</i>	<i>M. hirudinaceus</i> egg containing the acanthor larva with rostellar hooks is large, ovoid and has a thick, dark brown, textured shell egg of <i>O. canis</i> is relatively small, ovoid, brownish, and has a smooth, thick shell	Where pigs are kept in small sties or runs regular removal and suitable disposal of feces containing eggs will help in reducing the infection; older drugs such as carbon tetrachloride, tetrachlorethylene, and nicotine sulphate have been used; the drug of choice appears to be loperamid hydrochloride which at 1.5 mg/kg twice daily $\times$ 3 days kills 100 % adult and pre-adult worms without showing side effects; fenbendazole (► Nematocidal Drugs, Animals) at 20 mg/kg $\times$ 5 days and levamisole may also be effective; a single intramuscular dose of 0.3 mg/kg doramectin reduced <i>M. hirudinaceus</i> worm burden in naturally infected pigs by 62 %
Monkeys infection may be common in zoos	<i>Prosthenorchis elegans</i> <i>P. specula</i> eggs in feces are smaller than those of <i>M. moniliformis</i>	Insecticides and good sanitation will control the intermediate hosts (cockroaches, <i>Blattella germanica</i>); dithiazinine iodide has been effective; other drugs (see pig) may also affect adult worms and may be used by way of trial
Hedgehog adult worms of different species measure 0.5–12 cm in length	<i>Prosthenorchis rosai</i> <i>Nephridiorhynchus major</i> and others eggs in feces have a thick shell	Pathogenic effects of adult worms may be ulcerative enteritis, GI disturbance and peritonitis caused by perforation of intestinal wall; intermediate hosts are insects; prevention is not possible; treatment with fenbendazole (20–50 mg/kg $\times$ 5 days in feed), other benzimidazole carbamates (► Nematocidal Drugs, Animals), loperamid or levamisole may be used by way of trials

(continued)

Acanthocephalacidal Drugs, Table 1 (continued)

Host (other information)	Parasite (other information)	Control and treatment (nonproprietary name, miscellaneous comments)
Rodents (mice, rats) parasite has a worldwide distribution	<i>M. moniliformis</i> egg is larger than that of <i>M. hirudinaceus</i> , elongated oval, has a thick, smooth, clear shell	Strategic use of insecticides may control intermediate host (cockroaches) in laboratories; treatment of rodents is similar to that used with <i>M. hirudinaceus</i> (see hedgehog, above); infections have been reported on rare occasions in humans and are acquired by accidentally ingesting of beetles with food; adult worm has a pseudosegmentation of the body; adult female worm can reach >20 cm in length
Aquatic birds parasite has minor veterinary importance	<i>Filicollis anatis Polymorphus minutus</i> (syn. <i>P. boschadis</i>) eggs in feces are relatively small and spindle-shaped	Worldwide distribution; prevention is impossible because of the ubiquitously occurring freshwater isopods and other crustacean intermediate hosts; treatment is unknown but fenbendazole (20–50 mg/kg × 5 days in feed), other benzimidazole carbamates (► Nematocidal Drugs, Animals), and loperamid may be used by way of trial; acanthocephalan infections (<i>Centrorhynchus lancea</i> , <i>Mediorhynchus taeniatus</i>) have been reported in free-living houbara bustards in the United Arab Emirates
Finfish: ¹ non-predacious	^{1,2,4,5} <i>Pomphorhynchus laevis</i>	These acanthocephalans may cause heavy infections accompanied by high mortality in aquaculture - the selective breeding and raising of fish in “fish farms”; commercial fresh water or marine intensive fish farming in certain locations in Europe and particular in India and China may not only suffer disastrous economic losses caused by para sites but also considerable pollution of water by food and chemicals (see Anonymous, <i>Nature</i> 386: 105–110, 1997); in trout, loperamid infeed proved effective at 50 mg/kg/day × 3 days killing 100 % adult and preadult worms without obvious adverse effects; the drug is not licensed for food fish
² Predatory	^{3,5} <i>Neoechinorhynchus rutili</i>	
³ Freshwater	<i>N. rutili</i>	
⁴ Saltwater	⁶ <i>Acanthocephalus lucii</i>	
⁵ Brackish water	⁷ <i>A. anguillae</i>	
⁶ Perch, eel	^{4,8} <i>Echinorhynchus gadi</i>	
⁷ Salmonoid fishes	⁷ <i>E. truttae</i> , others	
⁸ Cod	⁸ <i>E. gadi</i>	

which are attached to the wall of the small intestine, cause diarrhea, GI disturbances, and ► [vomiting](#) but also serious complications, such as severe ulcerative enteritis or perforation of the bowel resulting in peritonitis. The pathogenic

significance of *M. hirudinaceus* is similar for pigs causing granuloma formation at the site of attachment in the small intestine, ► [weight loss](#) and, rarely in heavy infections, penetration of the intestinal wall resulting in fatal peritonitis.

Very important parasites of Central and South American **monkeys** are *Prosthenorchis elegans* (very common), and *P. spicula* (less common). These acanthocephalans are now found throughout the world where primates are kept in zoos or elsewhere in captivity and where they have introduced the parasites. In heavy infections there is diarrhea, ► **anorexia**, and debilitation often associated with death caused by perforation of the intestinal wall by adult worms.

There are two genera which may cause enteritis in **aquatic birds**, e.g., *Filicollis* (*F. anatis*) and *Polymorphus* (*P. minutus*). The intermediate hosts in both cases are crustaceans. Pathogenic effects produced by adult worms attached to the intestinal wall resemble those that are seen in mammals.

Pathogenicity of numerous **fish** acanthocephalans is species-specific and varies considerably. There are species which penetrate through the intestinal wall, thereby entering the body cavity of fish. Other species remain in the lumen of intestine, showing frequent or less frequent change of attachment site. Intermediate hosts are crustaceans, and various fishes may serve as paratenic hosts. In the fish industry disastrous economic losses may be due to acanthocephalans, especially when fish farming is practiced with overcrowded fish populations.

Prevention and Treatment

Prevention and treatment of ► **Acanthocephala** infections can be seen in Table 1, which are in general problematic. In man, usually *Acanthocephala* eggs are not passed with the feces since worms may not mature to adults. Diagnosis is made by x-ray examination or endoscopy. Serological tests are not available.

Acanthocephalan Infections

Attachment

Generally, acanthocephalans that have a short neck do not deeply penetrate into the host's

intestinal wall with their ► **praesoma**, i.e., they do not create lesions reaching as deep as the muscular layers of the intestinal wall (► **Acanthocephala**, Fig. 4). In contrast, many acanthocephalans possess a long neck which may comprise a bulbous as an inflated part of the neck (Figs. 1 and 2). The bulbous functions as a dowel enabling the worm to occupy a permanent point of attachment at one site. Long-necked species perforate the tunica muscularis or the whole intestinal wall of the hosts with their praesoma (Fig. 1). In small hosts with thin intestinal wall parts of the metasoma (Fig. 3) or entire worms may be found in extraintestinal positions. The perforation of the intestinal wall may be supported by proteolytic enzymes.

Cellular Host Responses

Successive Cell Assemblages

The specific composition of host cells accumulating at the worm's praesoma follows a certain sequence which is related to the worm's mode of attachment. During the first days p.i. only necrotic tissue surrounding the praesoma can be found. After about 3–5 days p.i. a belt of inflammatory tissue with haemorrhagic involvement starts forming (Fig. 4). From about 10 days p.i. onwards the further succession of cell assemblages depends on the type of attachment. At the praesoma of perforating species the inflammatory tissue becomes dominated by macrophages maturing into epithelioid cells and another belt of connective tissue which attains a blue colour in Azan-stained paraffin sections, starts forming (Fig. 3). Later on, this belt may become considerably reinforced and interspersed with fibroblasts and collagen fibres and an outer belt of connective tissue (Fig. 5b, c) sometimes consisting of plane collagen fibres (Fig. 5c) is built up. The attachment site of the eoacanthocephalan ► *Neoechinorhynchus rutili*, although non-perforating, is characterised by a pronounced accumulation of collagen fibres (Fig. 5a). In contrast, species with shallow attachment seem to change their point of attachment prior to the formation of connective tissue at the site of the

A

Acanthocephalan Infections, Fig. 1 Micrograph of a semithin section of *Pomphorhynchus laevis* (penetrating species) in a naturally infected adult chub (*Leuciscus cephalus*). The upper praesoma (e.g., *P* proboscis, *BU* bulbus; upper neck not visible) has penetrated the host's

peritoneal cavity (*PT*). The praesoma has become encapsulated by connective tissue (*CT*) which degenerates in close contact to the worm's anterior neck and its bulbus $\times 40$. (*BW* bulbus wall, *IL* intestinal lumen, *N* neck, *NC* necrosis, *T* trunk (metasoma))

temporary anchorage, and a concentric zonation of neoplastic tissue around the parasite's praesoma does not emerge. Haemorrhagic spots (Fig. 4b) may occur in all the tissue belts mentioned here.

Longitudinal Zonation of Defence Cells

Among perforating species like *Pomphorhynchus laevis* the chronic stage of infection not only reveals concentrically arranged belts of necrotic, inflammatory, and connective tissue (Fig. 1) but also a longitudinal zonation can be figured out. Near or inside the peritoneal cavity the necrotic belt is very conspicuous. It is very rich in lipids that seem to become absorbed by the worm's ► [tegument](#). In contrast, at the lumen side of the intestinal tube the necrotic belt almost does not exist and defence cells form a closely fitting belt of solid compensatory tissue (Fig. 1). The question arises whether this zonation is host- or parasite-induced. Taking also the histopathology of *N. rutili* into consideration (Fig. 5a) it appears that the described zonation of the host's tissue is largely brought about by the parasite.

Proboscis Hooks

Irrespective of the type of construction, i.e., whether a tegumental outer cover exists

(compare ► [Acanthocephala](#), Fig. 15) the hooks always provoke the most pronounced accumulation of granulocytes. In *N. rutili* the small roundish ► [proboscis](#) with its large hooks the attracting of granulocytes towards the hooks, and the surrounding tegument is very severe in salmonids and other fish during the acute initial phase of the infection and it has been suspected that this is induced by the parasite benefiting from it in aspects related to nutrition or attachment (Fig. 6b).

Infections in Fish, Birds, and Mammals

In contrast to the paucity of information available on many aspects of host–parasite interactions of acanthocephalans, these worms are very common in many wild-living vertebrates as well as cultured fish. Species like ► [Moniliformis moniliformis](#) can be easily kept in a laboratory in cockroaches and rats. It offers huge quantities of tissue and Surface Coat. So it would be very useful for physiological and molecular studies.

In fish hosts the inflammatory response is dominated by granulocytes (Fig. 4) and macrophages/epitheloid cells depending on the conditions described above. Usually eosinophils are the

Acanthocephalan Infections, Fig. 2 LM of an opened intestine of a domestic duck naturally infected with *Filicollis anatis*. The trunks (metasoma) of the worms can be inside the gut lumen whereas the praesomal bulb encapsulated by neoplastic tissue is seen at the outer side of the intestinal wall; The worm density of *Filicollis anatis* shown here potentially creates mortality among ducks

most abundant granulocytes (Fig. 4a) but in eels, for instance, eosinophilic granulocytes rarely occur and thus heterophilic granulocytes dominate in the tissue near the praesoma of *Paratenuisentis ambiguus* or other parasites of eel. Fish-specific melano-macrophages, also may occur near the acanthocephalan praesoma. Plasma cells, however, (documented from fish) also may occur but do not seem to play the same role as, for instance, in mammals. In fish immunoglobulins develop relatively slowly during the course of an infection, precipitins are rare, and the only immunoglobulin class produced is IgM being better at agglutination and complement activation than precipitation. Very little is known about the use of antibodies of fish against acanthocephalans.

In birds (ducks infected with *Filicollis anatis*, Fig. 2) heterophils represent the major granulocyte fraction (Fig. 4b). Macrophage giant cells frequently occur in the tissue near the parasite's praesoma, and also plasma cells are contained in it depending on the stage of infection.

In mammals a progressed stage of infection is accompanied by the abundance of plasma cells near the worm surface (Fig. 7b) after having passed through an acute phase of infection associated with a mass occurrence of eosinophilic and heterophilic granulocytes (Fig. 7a, c). In rats infected with *M. moniliformis* the occurrence of plasma cells up from about 10 d.p.i. (Fig. 7b) corresponds with the increase of worm-specific IgE-antibodies as described elsewhere.

Several fish researchers have often been amazed by the high intensities, often exceeding 100 specimens per gut, with acanthocephalans like the perforating species *Pomphorhynchus laevis*, being tolerated without showing external signs of disease.

In birds and mammals, however, different species of perforating acanthocephalans have been involved in ► **morbidity** and mortality, especially under elevated worm intensities as shown by a domestic duck infected with *F. anatis* (Fig. 2). This polymorphid palaeacanthocephalan also causes ► **weight loss**, ► **anaemia**, debility, apathy, and somnolence among infected ducks.

In mammals and birds the involvement of secondary infections and the infiltration of bacteria from the deep lesions into the peritoneal cavity seem to contribute to this pronounced pathology. In swine the sites of attachment of the perforating archiacanthocephalan *Macracanthorhynchus hirudinaceus* are marked on the outer surface by a caseous ► **nodule** with a reddened annulation around it. It frequently abscesses with bacterial involvement, which may lead to perforation of the gut wall. Human patients in China and Southeast Asia have suffered unbearable ► **abdominal pain** during the passage of the entire worm or parts of it into the peritoneal cavity which is accompanied by infiltration of eosinophils and neutrophils, massive ► **oedema**, and large quantities of serosanguineous exudate in the body cavity near the site of perforation. Prior to 1980 perforating

degranulation. (LY lymphocyte, SC surface coat of the worm's praesoma). (b) Inflamed and haemorrhagic loose neoplastic tissue of a naturally infected duck near the anterior bulb/proboscis of a *Filicollis anatis*. (ER erythrocyte, HG heterophilic granulocyte, CF collagen fibres)

acanthocephalans (mainly *Prosthenorchis elegans* and occasionally *Oncicola spirula*) infecting primates held in zoos were the cause of numerous fatal cases among these hosts. But since

then no further cases have been published, probably due to the resulting growing awareness of this threat in zoological gardens since then. The perforation canal through the intestinal wall

Acanthocephalan Infections, Fig. 5 Micrographs of connective tissue in the intestinal wall of fishes infected with acanthocephalans. (a) SEM showing the former point of attachment of a proboscis of *Neoechinorhynchus rutili* in the intestinal wall of a naturally infected rainbow trout. (c) TEM of firm connective tissue consisting of plane collagen fibres near the outer margin of the neoplastic tissue encircling the bulbous of a large specimen of the perforating species *Pomphorhynchus laevis* in a chub

Acanthocephalan Infections, Fig. 6 Light microscopical micrographs of sections of acanthocephalans and surrounding tissue of the fish hosts' intestinal wall. (a) Semithin cross section through the anterior metasoma of a young adult *Acanthocephalus anguillae* and surrounding intestinal plicae. The worm is surrounded by a “cloud” of cells and liquids leaking from the intestinal wall into the gut lumen. Also note the densely set, hyperplastic goblet cells in the mucosa (arrow). (b) Paraffin longitudinal section through the anterior third of a *Neoechinorhynchus rutili* in a naturally infected grayling (*Thymallus thymallus*). Note the huge inflammatory reaction around the worm's praesoma. (SC collagenous stratum compactum)

harbouring the parasite was filled with inflammatory exudate enriched with scattered masses of bacteria and acute peritonitis was diagnosed to be the cause of death in many cases reported by several authors. Less than 15 specimens of *P. elegans* are considered sufficient to cause mortality in squirrel monkeys.

In contrast to these descriptions from 3 perforating acanthocephalans, *M. moniliformis* with its superficial attachment (Fig. 8) does not create mortality among rats, and in these hosts as well as in accidental human cases where a worm had been measured to be 26.5 cm in length, the symptoms of morbidity are much less pronounced. All these findings suggest that the depth of penetration of an acanthocephalan species is an important criterion influencing the course of pathology at least in host–parasite associations involving mammals or birds as final hosts.

Praesoma Morphology Influencing the Host-Parasite Interface

The praesoma of eo- and palaeacanthocephalans is invested by a lipid surface cover (Acanthocephala/Integument, Fig. 11). It

Acanthocephalan Infections, Fig. 7 TEM of the proboscis surface and of surrounding host tissue of *Moniliformis moniliformis* in rats. (a) Acute phase of infection, 10 d.p.i. Eosinophilic and heterophilic granulocytes form dense populations near the praesoma. Large patches of the surface coat have detached from the worm. (b) Plasma cell out of a dense association of such cells near the surface of a worm, 60 d.p.i. (c) 10 d.p.i. infection. Note

the fine fuzzy structure of the surface coat still adhering to the worm's praesomal surface while other portions of it have detached (*DS* detached surface coat, *DE* degranulated eosinophilic granulocyte, *EG* eosinophilic granulocyte, *HG* heterophilic granulocyte, *SC* surface coat. *SL* ▶ striped layer of the tegument, *OS* osmiophilic substance deriving from the annular cleft around the "naked" hook)

probably fulfills defence functions but obviously also incorporates lipids from necrotic host tissue which then becomes absorbed by the parasite (▶ *Acanthocephala*, Fig. 10). Within this coat, osmiophilic films seem to be shed from the parasite's surface (▶ *Acanthocephala*, Fig. 12b). Whether these are loaded with peptides or substances deriving from defence mechanisms of the host will have to be proven in experiments.

The phenomenon of shedding (▶ *Capping*) of surface coat can be commonly observed from *M. moniliformis* in rats (Fig. 7a, c). Large patches of the fuzzy surface coat detach from the praesomal worm surface into the surrounding necrotic inflammatory tissue/exudate. It happens during the acute phase of infection associated with

a granulocyte response as well as later on when plasma cells accumulate at the praesoma. One may conclude that host's enzymes and/or antibodies bind to this coat until it is shed by the parasites. In transmission electron micrographs patches of detached coat attain a more coarsely structured and more electron lucent appearance compared to the ▶ *glycocalyx* still lining the surface (Fig. 7a, c).

Leakage of Liquids, Cells, and Debris from the Lesion

The phenomenon of leakage from the lesion created by a worm into the intestinal lumen has been documented in many acanthocephalans (Figs. 6a and 8). It seems to be most pronounced at the

Acanthocephalan Infections, Fig. 8 Semithin longitudinal section of the praesoma and anterior trunk of a 20-d.p. i.-specimen of *Moniliformis moniliformis* in a rat. Note the superficial attachment, the deep proboscis cavity (most of the proboscis is invaginated), the hyperplastic goblet cells (HG), and the efflux (EF) from the lesion into the intestinal lumen (RW spirally arranged muscle cords of the outer receptacle wall)

climax of the acute phase of infection at the point of attachment of perforating species (Fig. 6a). Having reached a progressed chronic stage, the opening of the lesion heading towards the intestinal lumen almost tightens up by the host so that the leakage decreases (Fig. 1). Most non-perforating species, on the other hand, seem to switch their site of attachment prior to a severe inflammatory reaction with an accompanying leakage.

Abrasion, Erosion, Compression

Usually the mucosal surface within the range of an acanthocephalan ► **metasoma**, also becomes mechanically affected by movements and the body pressure of the worms, especially close to the lesion. Also, many acanthocephalans possess

body spines which support a burrlike affiliation of parts of the metasoma with the mucosal surface which should have some scratching effect.

Increased Diameter of the Intestinal Wall

A local increase in thickness of the intestinal wall at the site of anchorage is well described in acanthocephalans. In addition also other parts of the host's gut which are not in contact with the worms may be enlarged in diameter.

Distention of the Intestine

The rat intestine in its length may be extended due to a single specimen of *M. moniliformis*. Also certain appendages like pyloric caeca were found to become almost doubled in diameter due to the acanthocephalans (*Leptorhynchoides thecatus*) inhabiting the caeca. Interestingly intestinal caeca seem to be a preferred environment of several intestinal helminths, and one acanthocephalan has been found to create its own caecal microhabitat. This species, *N. carpiodi*, also exhibits that social clustering exists among acanthocephalans. Up to 20 or more worms can be found together inside deep caverns surrounded by collagen capsules seen as expansions at the outer intestinal wall.

Occlusion of the Intestine

A few acanthocephalans such as *Macracanthorhynchus hirudinaceus* reach considerable size, i.e., more than half a meter in length. High worm burdens have been mentioned to have occluded the intestinal tube leading to mortality among piglets.

Negative Influence on Metabolic Parameters

As in other helminths which are better investigated than acanthocephalans one should expect that various physiological parameters of the hosts become negatively influenced by an acanthocephalan infection, especially under the influence of a co-stressor like insufficient energy supply or unsuitable temperatures. Indeed, growth, weight gain, and blood sugar concentrations of rats infected with *Moniliformis moniliformis* were most conspicuously altered when diets with low amounts of carbohydrates were offered. Among starlings experimentally

infected with moderate numbers of *Plagiorhynchus cylindraceus* only negative effects (on the weight of male host individuals) could be observed under deficient temperatures.

Fever

Elevated body temperatures due to acanthocephalan infections have been reported in domestic ducks as well as in primates and humans.

Goblet Cell Hyperplasia

Several authors have reported inflated goblet cells along the intestinal mucosa in hosts (fish, rats) infected with acanthocephalans, also their density was found to increase due to acanthocephalan infections (Figs. 6a and 8). Concerning primary infections of perforating acanthocephalans permanently remaining at one point of attachment, this defence measure might be ineffective. But young worms supplementing an established infestation as well as specimens of non-perforating acanthocephalans showing a non-sessile behavior, should be affected by an excess of mucins deriving from goblet cells.

Skeletal Deformations

Notes exist, that describe brown trout, heavily infected with different acanthocephalan species, to show deformed backbones and/or shortened gill operculae or fins. This may have to do with the recently detected very high absorptive capacity of acanthocephalans for calcium and other minerals.

Infections in Humans

Two species of archiacanthocephalans and three species of palaeacanthocephalans (► [Acanthocephala](#)) have been found in humans. Cases of *Macracanthorhynchus hirudinaceus* have been reported mainly in China and Thailand, of *Moniliformis moniliformis* in many tropical and subtropical countries. Specimens of *M. moniliformis* are located inside the intestine, where they reach sexual maturity. All other acanthocephalans recovered from humans do not reproduce in this accidental host. *Acanthocephalus*

rauschii, *A. bufonis*, and *Corynosoma strumosum* (parasites of fish, amphibians, and seals, respectively) have been obtained from human patients in Alaska (*A. rauschii* and *C. strumosum*) and Indonesia (*A. bufonis*). *A. rauschii* was located in the peritoneum, and the other two palaeacanthocephalans in the gut.

Infections with *M. hirudinaceus* and *M. moniliformis* usually occur among small children who, willingly or accidentally, ingest insects. In parts of Asia, however, where raw or undercooked insects are customarily eaten, adult humans also become infected; symptoms of infection such as weight loss, intermittent fever, bulging abdomen, diarrhea, and severe pain are well described. In a hospital in China 115 cases of acute abdominal colic due to *M. hirudinaceus* were reported over a period of only 3 years. Often *M. hirudinaceus* in humans occupies extraintestinal positions. The migration of this perforating acanthocephalan through the gut wall is very painful. An adult volunteer who swallowed infective larvae of *M. moniliformis* suffered from abdominal pain beginning from the 20th day after infection. It seems that *M. moniliformis* does not lead to a great inflammatory reaction; however, abdominal surgery on patients infected with *M. hirudinaceus* revealed a serosanguinous exudate in the peritoneum, inflamed parts of the intestine with ► [nodules](#) of up to 3 cm in diameter, and/or intestinal perforations. Thus, in humans both species show a pathogenicity similar to that in their major hosts, i.e., rats and swine (*M. hirudinaceus*) respectively.

Life Cycle

► [Acanthocephala](#).

Species

1. ***A. reconditum***: Adult worms parasitize in the subcutis of canids (prevalence rates up to 55 %), microfilariae are found in the blood, and vectors are fleas and mallophages. Distribution: South Europe, America, Asia, and Australia.
2. ***A. viteae***: Adult worms parasitize in the subcutaneous tissue of rodents (*Meriones*), larvae are found in the blood, and vectors are argasid ticks; distribution in deserts.
3. ***A. grassi***: Adult worms live in dogs (prevalence rates 1–5 %); microfilariae appear in the skin, prepatent period about 2–3 months. Distribution in South Europe. Vectors are ticks of the genus *Rhipicephalus sanguineus*.
4. ***A. dracunculoides***: Adult worms and their microfilariae live in dogs in South Europe and in Africa (prevalence rates of 1–2 %). Vectors are *Rhipicephalus sanguineus* ticks and → *Hippobosca* louse flies. Prepatent period is 2–3 months.

Acanthocheilonema Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Synonyms

Dipetalonema

Name

Greek: *acantha* = spine; *cheilos* = lip;
nema = thread

General Information

The species of the genus of the so-called Filarioidea (subfamily Onchocercidae) are distributed worldwide. Their adults live inside the connective tissues of dogs and relatives respectively in rodents. The unsheathed microfilariae are found

Acanthor is the first larva of ► [Acanthocephala](#) (Acanthocephala/Reproduction, ► [Acanthocephala](#)/Figs. 2 and 3). During the first equal cell divisions

Acanthor, Fig. 1 Schematic drawing of a hatched acanthor of the eoacanthocephalan *Paratenusentis ambiguus*. The frontal syncytium (FS) is rich in electron-dense vesicles (EV) as well as vacuoles containing electron-lucent mucus-like matter (VL). The central syncytium (CS) harbors condensed nuclei (CN) and a few decondensed nuclei (DN). The epidermal syncytium (ES) forms most of the body including fused crypts of the outer membrane which contain round electron-dense granules. The surface of the larva is armed with hooks (H) and body spines (SP). The two retractor muscles (R) enable the larva to perform invaginations of the anterior body. The hind body may contract itself by the action of the ten longitudinal muscle cords (LM, only two are drawn); LI lipid drop (Reitze and Taraschewski unpublished)

after fertilization, two polar bodies usually appear at the end of the embryo that will become the anterior end of the acanthor. Further, equal and unequal divisions show a kind of spiral cleavage resulting in micromeres and macromeres. In a later stage, the central nuclear mass (inside the central syncytium) appears. However, there is no formation of a digestive tract at any phase of development. In addition, the very early embryo

Acanthor,

Fig. 2 Schematic drawings of the eggshells of Palaeacanthocephala (a), Archiacanthocephala (b), and a neoechinorhynchid eoacanthocephalan of the genus *Neoechinorhynchus* (c). E eggshells (envelopes), G granular interstices, AC acanthor. (a) Note the filiform outgrowth of the second eggshell. (b) The second eggshell creates a thick mesh of amorphous matter intermingling with the first interstice. (c) Note the existence of five eggshells and five interstices, respectively. The two outermost interstices are loaded with carbohydrates. The eggshell E2 seems to keep the E0 eggshell in position. The E3 eggshell is just a membrane

attains a syncytial organization. Thus, it is difficult to decide what is ectoderm, endoderm, or mesoderm. During the course of development, the embryo detaches from the floating ovary, and the single eggshell differentiates into the different envelopes.

Mature acanthors consist of three syncytia, the central ► **syncytium** (median), the epidermal syncytium (caudal), and the frontal syncytium (Fig. 1). Within the central syncytium, there are ten subepidermal longitudinal muscles and two more centrally located retractor muscles. According to descriptions of Albrecht et al. from acanthors (of three species) that were still inside the mother's body cavity and enclosed by eggshell

envelopes, the subepidermal muscles are connected via cytoplasmic bridges with the central nuclear mass. However, in hatched acanthors of *Paratenuisentis ambiguus* collected from the gut of its crustacean intermediate host, no connections between the central syncytium and the subepidermal muscles could be found; the muscles were part of the epidermal syncytium (Fig. 1). So probably the bridges described may get lost during the final maturation of the acanthor or the hatching process. The central nuclear mass contains condensed as well as decondensed nuclei. The latter are also found in the epidermal and the frontal syncytium (Fig. 1). The epidermal syncytium forms the outer surface and most of the

Acanthor, Fig. 3 TEMs of sections through eggshell envelopes and interstices enclosing acanthors of palaeacanthocephalans treated in different fashions. (a) Egg of ► *Acanthocephalus anguillae* incubated according to the electron microscopical PAS method of Thiéry in a mode to visualize glycogen (dark granules in the acanthor). Also note the four eggshells (E1–E4) and the transversally sectioned subepidermal longitudinal muscles (LM); FP filiform protuberance of E2. (b) Egg of ► *Polymorphus minutus* incubated with anti-keratin and subsequently with a second antibody labeled with colloidal gold. Note the gold granules on eggshell E2 and its outer filiform

protuberances indicating keratin in the second envelope. This section does not show the granular interstice between the third and the fourth envelope. As can be seen under (a), the width of the interstices is different. AC acanthor. (c) Innermost envelope (E4) and acanthor of *P. minutus* after incubation with lectin wheat germ agglutinin (coupled with colloidal gold granules) in a mode that chitin is visualized. Note the gold label on E4, also the crypts of the acanthor's outer membrane (CM), and the glycogen granulation between the mitochondria and the vacuole of electron-lucent content (VL) (probably mucus)

larva's body. It contains numerous ► **vacuoles** with mucus-like electron-lucent content which are concentrated near the surface of the anterior half (Fig. 1). In acanthors of *P. ambiguus*, the crypts of the outer membrane are fused underneath the larva's surface and harbor electron-dense granules which may have a function during the penetration of the larva into the hemocoel of the intermediate host. The electron-dense vesicles as well as the vacuoles with electron-lucent content inside the frontal syncytium could probably also be involved in the task of penetration,

chemically supporting the action of the hooks. Stimulated acanthors of *Moniliformis moniliformis* have been found to discharge chitinase, but this enzymatic activity has not been localized at the acanthor's body. Hooks are most prominent at the anterior surface and decline in size toward the larva's posterior end (Fig. 1). Acanthors are rich in glycogen in the ► **cytoplasm** between the muscles, nuclei, ► **mitochondria**, and inclusions (Fig. 3a).

Mature acanthors of acanthocephalans are enclosed by four eggshells separated by

Acanthor, Fig. 4 Micrographs showing envelopes, interstices, and an acanthor (B) of the archiacanthocephalan *Macracanthorhynchus hirudinaceus*. (a) The ultrathin section has been incubated with chitinase and subsequently with lectin wheat germ agglutinin coupled with gold granules. The innermost envelope E4 therefore does not show a chitin-gold-label as it would without the enzyme treatment. According to competition experiments with *N*-acetylglucosamine and triacetyl chitotriose, it becomes evident that the partly intense label in the granular interstices is due to different carbohydrates but not chitin. The acanthor is not seen. Note that E1 and E3 are tripartite; G1–G4, granular interstices separating the envelopes; E1–E4, envelopes. (b) Light microscopical micrograph of an egg that has been incubated in sodium dodecyl sulfate (SDS) and dithiothreitol (DTE) to extract proteins including keratin. Consequently, the outer two envelopes swell considerably and eventually rupture due to an increase of the osmotic pressure. Therefore, the acanthor seen still enclosed by the keratin-containing E3 envelope and the E4 envelope that

interstices containing granular electron-lucent material (Figs. 2, 3, and 4a). However, eggs of *Neoechinorhynchus* species become complemented by a fifth envelope (E0) creating a fifth voluminous outer interstice (Fig. 2c). The outermost, first envelope seems to derive from the “fertilization membrane.” Usually, it is thin but can be reinforced by outgrowths of the underlying eggshell (Figs. 3b and 4a). This envelope (E2) was found to contain keratin in all three groups of the Acanthocephala. In palaeacanthocephalans, it forms more or less filiform outgrowths (Figs. 2a and 3a, b) entangling with algae or leaves (the food substrates of the intermediate hosts) once the outermost envelope has disintegrated in the water. In archiacanthocephalans, the second eggshell is interspersed with the respective outermost interstice and seems to function in protecting the egg from desiccation and other negative outer influences (Figs. 2b and 4a). Among archiacanthocephalans, the underlying tripartite third envelope also comprises keratin, while eoacanthocephalans and palaeacanthocephalans do not have keratin in this eggshell. The fourth, innermost eggshell contains *chitin* among palaeacanthocephalans and archiacanthocephalans (Fig. 3c). In eoacanthocephalans, however, this innermost eggshell lacks chitin. The interstices contain carbohydrates which together with the envelopes seem to have different functions.

As a general rule, the outer envelopes and interstices appear to be ecologically related, accomplishing functions in parasite transmission, etc. In archiacanthocephalan eggs, the outer part of the eggshell swells when exposed to digestive influences so that the inner part containing the acanthor is passively released (Fig. 4b). The interior envelopes (Figs. 2, 3, and 4a) seem to be systematics related and obviously fulfill tasks belonging to the principle requirements of the acanthor.

Acanthor, Fig. 4 (continued) has chitin “shoots” out of its enclosure, suggesting that the digestive activity in the gut of the intermediate host largely contributes to the hatching process of the acanthor

Name

Greek: *acari* = ► [Mites](#).

Acarina

Classification

Order of ► [Arthropoda](#).

General Information

The order Acarina, including ► [mites](#) and ► [ticks](#), contains numerous economically and medically important species that are parasitic on humans, domesticated or hunted animals, and crops, food, etc. Unlike other chelicerates, members of the Acarina lack a visible body division. Thus, the abdominal segmentation has disappeared and the abdomen has fused with the praesoma; the portion of the body on which the legs are inserted (the podosoma) is broadly joined to the portion of the body behind the legs (the opisthosoma) to form the ► [idiosoma](#) (Fig. 1). Another general feature of the group is the appearance of the anterior (head) region carrying the mouth parts (a pair of ► [chelicerae](#) and of ► [pedipalps](#)), this region being called the capitulum or gnathosoma. The chelicerae and pedipalps are variable in structure, depending on their function in the different groups (Argas, Fig. 1, ► [Ixodes](#), Fig. 1, ► [Mites](#), Fig. 1, ► [Neotrombicula autumnalis](#), Fig. 1). Chelicerae may appear needle-like for piercing the skin of

hosts or toothed (as in ► [ticks](#)) for anchoring to the ► [integument](#) of the host.

System

The classification of the Acarina, which as adults have four pairs of legs, is still a matter of controversy; with respect to the parasitic stages, the following system, which is based on the location of the openings of the tracheal system (stigma or spiracle), covers all parasitic species:

Subphylum: ► [Chelicerata](#).

Class: Arachnida.

- Order: Acarina.
- Suborder: Metastigmata (ticks; large species with recurved teeth, a pair of tracheal ► [spiracles](#) is located behind third or fourth coxae).
- Family: ► [Argasidae](#) (Argas).
- Family: ► [Ixodidae](#) (► [Ixodes](#)).
- Suborder: Notostigmata (large leathery primitive free-living ► [mites](#); four pairs of spiracles behind the fourth coxae).
- Suborder: Tetrastigmata (large predatory mites, two pairs of spiracles: one pair by the third coxae, the other behind the fourth coxae).
- Suborder: Mesostigma (parasitic and free-living mites; a pair of spiracles behind third or fourth coxae).
- Family: Dermanyssidae (► [Mites](#)).
- Family: Liponyssidae (► [Mites](#)).
- Suborder: Prostigmata (trombidiform mites with a pair of spiracles located anteriorly near mouth region; many free-living predatory species and some parasitic families).
- Family: ► [Demodicidae](#) (► [Mites](#)).
- Family: Trombiculidae (► [Neotrombicula autumnalis](#)).
- Suborder: Astigmata (mites without spiracles, including storage-, scabies-, mange-, and itch-mites).
- Family: ► [Acaridae](#)

Acarina,

- Family: Glyciphagidae
- Family: ▶ **Sarcoptidae** (▶ **Mites**).
- Suborder: Cryptostigmata (oribatid or beetle mites; typical spiracles absent, but the tracheal system is usually associated with the basis of the first and third pairs of legs).

Acariosis, Animals

Several ▶ **mites** infest animals and cause significant dermatologic diseases. These may be occasional parasites e.g., harvest mites (*Trombicula*) or obligatory parasites like ▶ **Sarcoptes** and ▶ **Demodex** genera. Mites may be free-living on the surface of the skin (*Cheyletiella*, ▶ **Chorioptes**), superficial burrowers (▶ **Sarcoptes**) or may penetrate more deeply (*Demodex*). The parasitic mites of the families ▶ **Sarcoptidae** and Psoroptidae, known as

“▶ **mange mites**,” generally give rise to well-defined dermatoses. The lesions are the result of mechanical damage to the skin and probably also of hypersensitivity reactions to toxic secretions (▶ **Pathology**, Fig. 30).

▶ **Sarcoptes scabiei** (▶ **Sarcoptic Mange**) occurs commonly in pigs, dogs and cattle; and more rarely in horses, sheep, goats and cats. The so-called feline ▶ **scabies** is caused by ▶ **Notoedres cati**. The several varieties of ▶ **Sarcoptes scabiei** may represent strains of the same mite which have become more adapted to particular hosts. The mites burrow into the skin. It has long been suspected that antigens from the mites themselves, their faeces, or their moulting and hatching fluids are responsible for the allergic reactions observed. Clinical signs are similar in all species and consist of a papillar eruption accompanied by severe ▶ **pruritus**. The intense scratching caused by the pruritus may lead to ▶ **alopecia**, secondary bacterial infections, lichens

and hyperpigmentation. The skin becomes thickened in severe cases. Clinically affected animals may become debilitated and lose weight or fail to properly gain weight. Feed efficiency is reduced and the hide may suffer considerable damage. Severely affected pigs may also become anaemic. The distribution of the lesions is characteristic in the various hosts.

Psoroptic mange is a serious disease in cattle and sheep, less so in horse and goats. The causative mites are species of ► *Psoroptes* and are host-specific. Mites penetrate the epidermis to suck body fluids, and cause a local reaction with formation of vesicles. The exudate from the vesicles coagulates and dries on the skin surface, resulting in the formation of a ► **crust** or scab of varying thickness. The mites move to the edge of the scab, and the lesion increases in size. There is marked pruritus, and scratching results in alopecia, erosions and ► **lichenification**. Lesions usually begin in areas thickly covered by hair or wool. Debilitation, reduced productivity and occasionally death may follow severe infestations. In goats *Psoroptes cuniculi* is known as the “earcanker” mite because of its predilection for the ear (causing otitis).

Chorioptic mange occurs commonly in cattle, sheep and horses, and more rarely in goats. The *Chorioptes* mites are host-specific and live on the surface of the skin. Generally, it is a less severe condition than psoroptic or sarcoptic mange. Lesions consist of alopecia, erythema, excoriations and (small) crusts associated with pruritus. The mites have a predilection for the perineum, udder, caudal areas of thigh, rump and feet. Lesions caused by *Chorioptes equi* start as a pruritic dermatitis affecting the distal limbs around the foot and fetlock. A moist dermatitis of the fetlocks develops in chronic cases.

► *Otodectes cynotis* is an obligate parasite of the external skin surface, mainly the external ear canal of cats and sometimes dogs. The major lesion is thus otitis externa.

Demodex spp. lives in the hair follicles and sebaceous glands of dogs, cats, cattle and goats. Demodicosis is of clinical importance in dogs. It is

less common in cats and other animals. Mites are often present on healthy animals without causing obvious lesions, but heavier infestations produce mechanical damage to the skin. As the mites multiply in hair follicles and sebaceous glands, the hairs fall out. Enlargement and rupture of adjacent follicles and glands leads to cyst formation. Secondary pyoderma associated with staphylococcal infection is a common complication in the dog. Skin lesions in this animal may range from small localised patches of alopecia, in which the skin may appear normal, to more generalised dermatitis with loss of hair, thickening and discoloration of the skin. In the pustular form of the condition, small pustules are formed in the hair follicles. Dogs with generalised demodicosis may have a concurrent pododemodicosis, which is characterised by interdigital ► **erythema** and alopecia or interdigital furunculosis with associated ► **oedema** and pain. Pododemodicosis may be the only manifestation of the disease. In cattle and goats *Demodex* lesions consist of small elevated ► **nodules** of varying size. Most lesions appear on the shoulder, head and neck region. Nodular demodicosis is characterised by the permanent formation of new nodules when the older ones disappear. Nodules arise when granulomatous inflammation is complicated by secondary bacterial infection.

Other ectoparasitic mites include ► *Dermanyssus gallinae*, *Lynxacarus radovsky*, *Trombiculidae* (chiggers) and *Cheyletiella yasguri*, *C. blakei* in dogs and cats, and *Psorogates ovis* in sheep. Clinical signs include erythema and pruritic papulocrustous eruptions. Cheyletiellosis in dogs and cats is typically more severe in young animals, with the primary lesion being scaling over the dorsal midline. Pruritus is variable.

Acceptable Daily Intake

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Synonyms

ADI

Definition

Dose of a drug residue in edible tissues, such as meat, various organs, and fat, which during the entire lifetime of a person seems to be without obvious risk to health based on all toxicological data known at the time.

General Information

The ADI for humans may be determined by applying a safety factor of 1:100 or a safety factor of at least 1:1000 in case of a teratogenic drug. Therapeutic claims made by the manufacturer must coincide with safety and tissue residue data for the drug approved by government regulatory agencies (► [Chemotherapy](#)).

Accidental Host

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Humans or animals that become occasionally infected and which are not regularly involved in the life cycle of a parasite.

Acephal

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Greek: *a* = not, *kephale* = head; the term means without a head, e.g., it describes appearance of the larvae of flies (Brachycera).

Acetabulum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Holdfast organ in ► [tapeworms](#), ventral sucker in ► [trematodes](#), and attachment point of *os ileum*, *os pubicum*, and *os ischium* in the human skeleton.

Acetylcholine-Neurotransmission-Affecting Drugs

Mode of Action

Figure 1.

Structures

Figure 2.

Organophosphates

Important Compounds

Dichlorvos, Diuredosan, Frento, Metrifonate, Coumaphos, Haloxon, Naphthalophos, Vapona.

Synonyms

Dichlorvos: Atgard, Dichlorman, DDVP, Equigard, Equigel, Task.

Diuredosan: Uredofos, Sansalid.

Metrifonate: Trichlorphon, Anthon, Bilarcil, Combot, Dipterex, Difrifon, Dylox, Dyrex, Mastotem, Néguvon, Tugon; in: Bubulin, Combotel, Dyrex T.F., Equizole, Néguvon A, Telmin B.

Coumaphos: Asuntol, Baymix, Co-Ral, Meldane, Muskatox.

Haloxon: Eustidil, Halox, Loxon; in: Haloxil.

Naphthalophos: Amdax, Maretin.

Clinical Relevance

Metrifonate was introduced as insecticide in 1955. It exerts activity in ► [Taenia solium](#) ► [neurocystercosis](#). Diuredosan is active against *Taenia* spp., ► [Dipylidium caninum](#), *Mesocestoides corti* and is only slightly active against *Echinococcus granulosus*. Fospirate is active against *T. hydatigena*.

The antitrepatodal activity of metrifonate is directed against ► [Schistosoma haematobium](#), and is only slightly active against *S. mansoni* and ► [S. japonicum](#). Metrifonate is one of the drugs recommended by the WHO for the treatment of urinary schistosomiasis and present in the current Model List of Essential Drugs. For use in ruminants organophosphates had been available only in a limited number of countries. They are generally not as effective as the broad-spectrum anthelmintics and also have a lower therapeutic index. Haloxon, trichlorphon, coumaphos, naphthalophos and crufomate had been used in cattle, haloxon in sheep, dichlorvos in pigs, dichlorvos and trichlorphon in horses, and coumaphos in poultry.

Molecular Interactions

Metrifonate is unstable in aqueous solutions, and a spontaneous, nonenzymatic transformation into various compounds takes place. One of the degradation products is dichlorvos, which exerts high biological activity. Acetylcholinesterase (AChE) from helminths as target for organophosphates was first explored in the late 1950s.

Acetylcholine-Neurotransmission-Affecting Drugs, Fig. 1 Model of the action of drugs interfering with acetylcholine-mediated neurotransmission

Metrifonate has in vitro activity against ► *Ascaris lumbricoides* by the inhibition of AChesterases and cholinesterases resulting in an impairment of the action of the neurotransmitter acetylcholine (Fig. 1). AChesterase in ► *nematodes* is inhibited at very low concentrations of 10^{-13} M. This leads to an indirect permanent stimulation of excitatory neuromuscular transmission mediated by acetylcholine, followed by a continuous depolarization of the postsynaptic junction resulting in a spastic paralysis. In general, a complete paralysis of the oral sucker is induced at lower metrifonate concentrations than those required to produce complete paralysis of the body musculature. The prolonged paralysis of the intestinal musculature

leads to an interruption of peristaltic movements and a starvation of the parasite. The differences in metrifonate susceptibility among schistosome species are explained by differences in the amount of AChesterase located on the surface of adult schistosomes. Thus, *Schistosoma haematobium* teguments contain up to 20 times, and *S. bovis* teguments up to 6.9 times, higher AChesterase activity than *S. mansoni* teguments. These quantitative differences correlate well with the relative sensitivities of these species to metrifonate. There is presumably an association of the tegumental AChesterase and nACh receptors located on the dorsal surface of the adult males which may be responsible for the glucose import into

Acetylcholine-Neurotransmission-Affecting Drugs, Fig. 2 Structures of drugs affecting nicotinic neurotransmission

schistosomes. Thus, the surface and not the muscle AChE functions as the primary target of the metrifonate action.

The antinematodal activity of metrifonate is low. It has little activity against *Trichuris vulpis* and some activity against ► [roundworms](#) and ► [hookworms](#).

Metrifonate also has antifilarial activity, which is directed against microfilariae (► [Inhibitory-Neurotransmission-Affecting Drugs](#),” Table 1) and only to a minor degree against adult worms. Some organophosphates exert strong activity against *Litomosoides carinii* microfilariae. Metrifonate and fenthion are effective against

microfilariae of ► *Dirofilaria immitis*. There is no effect on developing stages of *D. immitis*, *L. carinii*, and ► *Acanthocheilonema viteae* by organophosphates. In cats metrifonate has adulticidal effects. In addition, metrifonate has been used in combination with different antinematodal drugs because of its activity against *Gasterophilus* spp. (► **Microtubule-Function-Affecting Drugs**, Table 2).

The action of organophosphates against *L. carinii* microfilariae is complicated. The inhibition of AChEsterase which is important for effect against gastrointestinal nematodes and *S. haematobium* is presumably not the mode of action of these compounds against microfilariae. Microfilariae do not become primarily immobilized in vivo by haloxon or metrifonate. Instead, there is an induction of organophosphate-mediated adherence of phagocytic cells to the microfilariae observable resulting in a final killing of larvae. This effect looks similar but not identical to that of DEC (► **Inhibitory-Neurotransmission-Affecting Drugs**, Table 1; ► **Membrane-Function-Disturbing Drugs**, Fig. 1).

Furthermore metrifonate possesses insecticidal activity. In this indication metrifonate is known as trichlorphon (=Dipterex or Dylox).

Resistance

Until now resistance against metrifonate is not known. However, against coumaphos and naphthalophos there are resistant ► *Haemonchus contortus* strains in sheep and goats which lead to the ineffectivity of these organophosphates.

Ethanolamines

Important Compounds

Bephenium, thenium, methyridine.

Synonyms

Bephenium: Alcopar, Francin.

Thenium: Bancaris, Canopar; in: Ancaris, Thenatol.

Methyridine: Dekelmin, Mintic, Promintic.

Clinical Relevance

The antinematodal activity of bephenium is directed against *Ascaris lumbricoides*, ► *Ancylostoma duodenale*, ► *Trichostrongylus*.

Molecular Interactions

Several drugs belong to the class of ethanolamines such as bephenium, thenium, and methyridine. They have structural similarity to acetylcholine or nicotine and act as agonists of the acetylcholine receptor (Fig. 1) by binding to the acetylcholine receptors in the nerve cords of the nematodes. The compounds are not inactivated by AChEsterase. The result of the agonistic activity is the induction of depolarization and a permanent muscle contraction or spastic paralysis in the worms. The specific toxicity of these compounds is explained by the greater affinity to the parasite's receptors compared to the host receptors. At high concentrations they are also toxic for the host.

Pyrantel, Morantel, Oxantel, Levamisole, Tetramisole

Synonyms

Pyrantel pamoate: in Antiminth, Banminth, Cobantril, Combantrin, Felex, Helmex, Imathal, Nemex, Piranver, Pyraminth, Strongid T; in: Dosolid, Trivexan, Welpan.

Pyrantel tartrate: in Banminth, Exhelm, Nemex, Pyreguan, Strongid.

Morantel: in Banminth II, Ibantic, Paratec; rumatel; in: Banminth D, Equiban.

Oxantel pamoate in: Quantrel.

Levamisole: Anthelpor, Aviverm, Bionem, Cevasol, Chronomintic, Citarin-L, Cyverm, Dilarvon, Duphamisole, Ketrax, Levadin, Levamisol "Virbac" 10 %, Levipor, Levacide, Levasole, Narpenol 5, Nemacide, Nilvern, Ripercol L, Solaskil; in: Ambex, Nilvax, Nilzan, Spectril.

Tetramisole: Anthelvet, Ascaridil, Citarin, Nemicide, Ripercol, Spartakon.

Clinical Relevance

Pyrantel has some anticestodal activity. It is effective against ► **tapeworms** in horses in field trials,

Acetylcholine-Neurotransmission-Affecting Drugs, Fig. 3 Route of uptake of anthelmintics by nematodes (Representation of the morphology of a sexually mature

female worm according to Cox (1996) In: Cox FEG (ed) *Modern Parasitology*, Blackwell Science, 2nd edition)

but the efficacy against *Anoplocephala perfoliata* is uncertain. However, pyrantel and levamisole are mainly used in the treatment of nematode infections in human and veterinary medicine (“► **Microtubule-Function-Affecting Drugs**,” Table 1). In addition, levamisole has microfilaricidal activity as shown in *Litomosoides carinii* infected *Mastomys coucha*. There is also microfilaricidal efficacy against ► *Wuchereria bancrofti* and ► *Brugia malayi* in man (“► **Inhibitory-Neurotransmission-Affecting Drugs**,” Table 1). Of interest is the topical application (eye drops) of levamisole. Levamisole has no effect against microfilariae of ► *Onchocerca volvulus*. The side effects are similar to that of DEC treatment. Embryotoxic activity is observed in different filarial infections.

Molecular Interactions

The mode of action of these drugs relies on their anticholinergic activity. Levamisole is chemically an imidazothiazole, while pyrantel, morantel, and oxantel are tetrahydropyrimidine derivatives. They are simultaneously agonists and antagonists of the nematode ACh-receptors. Pyrantel acts as a nicotinic agonist on the acetylcholine receptor in the nematode *Ascaris suum* (Fig. 1). It induces a depolarization and an increase in input conductance of the muscle membrane due to sodium and potassium. Pyrantel leads to a spastic paralysis of

► *Angiostrongylus cantonensis*. Levamisole is taken up by the nematodes via the cuticula, whereas the uptake of pyrantel and morantel occurs via the oral route (Fig. 3). In patch-clamp studies these nicotinic anthelmintics open cation channels nonselectively. Each channel has a characteristic conductance. There are variations of conductance between channels recorded from different patches in the range 19–60 pS. The mean open time of the channels varies with the anthelmintic in the range of 0.5–2.5 ms. These nicotinic anthelmintics act on the receptor with properties similar to, but not identical with, the nicotinic receptors in mammalian and vertebrate hosts because of pharmacological differences. Indeed, there is no significant action of levamisole on host muscle.

The antagonistic effects of levamisole, pyrantel, morantel, and oxantel may be explained by the fact that these molecules are too large to pass through the nicotinic acetylcholine receptor channel. However, they pass through the extracellular opening of the channel and lead to a blockage at the so-called middle ring of the channels. Thus, the middle ring of ACh-channel acts as a bottleneck for passing molecules. Thus levamisole, pyrantel, oxantel, and morantel induce a voltage-sensitive channel block at the nicotinic receptors in *A. suum* at higher concentrations.

The antifilaricidal action of levamisole relies presumably on an immunomodulatory effect. Thereby, cell-mediated immunity is stimulated, resulting in a generally depressed cellular response in microfilariaemic hosts. The levamisole-dependent immunostimulation is observed at low doses. So far there are no experimental data on enhanced immune reactions after levamisole treatment. There is only one report on enhanced filarial antigen-induced inhibition of the migration of macrophages in *B. malayi* infected *Mastomys coucha*.

Besides antiparasitic activities levamisole exerts antitumor activity.

Resistance Against Levamisole

Resistance against levamisole occurs in a variety of nematodes in sheep, goats, cattle, and swine. The mode of resistance against levamisole is yet unclear. The heterogeneity in the types of nicotinic receptors are thought to facilitate the development of anthelmintic resistance against nicotinic drugs and perhaps to other anthelmintics that act on membrane ion channels. Thus, in *Oesophagostomum dendatum* up to four nicotinic receptor types are present. The α -chains of the nicotinic ACh-receptor from susceptible and resistant *Trichostrongylus colubriformis* and *H. contortus* show no difference in amino acid sequence. There are different effects on the hatching of eggs between levamisole/morantel-susceptible, levamisole/morantel-resistant and morantel-resistant strains of *H. contortus* and *T. colubriformis* in the presence of levamisole, morantel, or pyrantel. Compared to adult susceptible *H. contortus*, five- to sixfold higher concentrations of ACh and other nicotinic agonists are necessary to cause equivalent contractions in levamisole/morantel-resistant worms. It is assumed that levamisole/morantel resistance is due to a reduced number or sensitivity of cholinergic receptors in resistant *H. contortus*. Levamisole-resistant mutants of *Caenorhabditis elegans* lack ACh-receptors and there is no response to the nicotinic agonists

acetylcholine, nicotine, carbamyl chloride, or levamisole, which in susceptible *C. elegans* cause contractions. The binding of cholinergic agonists varies between levamisole-susceptible and levamisole-resistant *C. elegans*.

Paraherquamide

Clinical Relevance

Paraherquamide is an oxindol alkaloid metabolite of *Penicillium paraherquei*. It has antiparasitic activity and was first reported in rodent models. It is highly efficacious at a single oral treatment at dosages above 0.5 mg/kg against adult trichostrongylides in sheep and in addition against L4 larvae of *Cooperia* spp. Moreover, it is effective against ivermectin- and benzimidazole resistant *Haemonchus* and *Trichostrongylus* strains. In calves paraherquamide is effective against adult stages of nine common gastrointestinal and lung nematodes at single oral dosages of 0.5, 1.0, 2.0 or 4.0 mg/kg. However, *Cooperia punctata*, the dose-limiting species, was affected only at the highest dosage of 4.0 mg/kg to 89 %. The compound is not toxic in ruminants up to a dosage of 10 mg/kg, but three dogs given an oral dose of 10 mg/kg had severe intoxications within 30 min of dosing and two animals died within 2 h. On the basis of available data, for a broad-spectrum therapeutic paraherquamide has a therapeutic index of less than 3 at the dosage of 4 mg/kg and is thus inferior to ivermectin. As a narrow spectrum therapeutic used at a dosage of 0.3 mg/kg paraherquamide has a therapeutic index of 33 and could be thus useful as an antiparasitic agent if used in combination with an integrated approach to control resistant parasites.

Molecular Interactions

Paraherquamide is an extremely potent competitor at the α -bungarotoxin binding site at the nicotinic acetylcholine receptor in insects. It is also a competitor at the phenothiazine binding site. However, the real mode of action in nematodes has to be elucidated.

Achilles' Heel

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

This term refers to a weak point of a parasite or another organism, which make them vulnerable against aggressors or aggressive substances. The name has its origin in the Greek Troja-war-tale of the hero Achilles (son of Peleus and goddess Thetis), who was killed by an arrow (shot by Paris) entering his heel. This heel was the only vulnerable place on his body. Thus the arrow was steered by god Apoll, who was the protector of the town Troja.

Achoetandrus rufifacies

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

This hairy maggot blowfly is a medically important species in Europe and Asia (especially in Malaysia and Thailand) but also in Australia and USA and Canada, since it was documented as carrier of agents of diseases, such as *Escherichia coli*, *Klebsiella ozaenae*, *Proteus vulgaris*, *Pseudomonas fluorescens*, *Burkholderia pseudomallei*, several worm eggs (*Ascaris*, *Trichuris*, *Taenia*, *Hymenolepis*), or protozoan cysts (*Entamoeba histolytica*, *Giardia lamblia*). Skin of immotile or dead humans is also penetrated by larvae, and thus these data can be used in forensic investigations.

Achroia grisella

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Small species of the butterfly group moths that parasitize in stocks of bees.

Achromaticus quadrigemina

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Species of blood parasitizing protozoans (genus *Babesia*) of mice. Synonym for *B. quadrigemina*. See ► [Babesia](#).

Achteres

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Genus of ectoparasitic crustaceans attached to fish skin, e.g., *A. percarum* on perch.

Achtheinus

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Genus of caligid ectoparasites (crustaceans)
 on fish.

Acini

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Grape-like arranged salivary glands of ► [ticks](#).

Acidocalcisomes

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Acidic Ca^{2+} storage compartment in
 trypanosomatids, e.g., *Leishmania mexicana*,
Trypanosoma cruzi, and ► [Apicomplexa](#)
 (► [Toxoplasma gondii](#)). They are also rich in
 phosphorous, Ca^{2+} , Mg^{2+} , and Zn^{2+} and have a
 number of pumps and exchangers involved in
 their homeostasis.

Acoleidae

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Family of cyclophyllidean tapeworms parasitiz-
 ing in birds.

Acidosis

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Decrease of the blood pH below 7.25. This symp-
 tom may occur during severe malaria tropica
 being found in about 0.4 % of the patients.

Acollé Stages

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name

French: *acoller* = to fix something by a glueing
 material. The name describes *Plasmodium*
falciparum and *P. vivax* stages, which are tightly
 fixed at the inner side of the membrane of an
 infected erythrocyte.

Acquired Immunity

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Infections with some parasites (e.g.,
► *Balantidium coli*, ► *Plasmodium* species,
► *Schistosoma* species, *Trichomonas* species)
may induce immunity so that reinfection remains
less severe.

Acquired Immunodeficiency Syndrome (AIDS)

General Information

► [Phasmids](#) are generally absent; amphids are postlabial and variable in shape, cephalic organs setiform to papilloid; setae and hypodermal glands usually present, hypodermal cells uninucleate; excretory organ, if present, single-celled; caudal glands mostly present; usually two testes in males; ► [cuticle](#) four-layered.

Adhesins

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

From Latin *adhaerere* = to become attached to something.

This term describes surface proteins of motile parasitic stages (merozoites, sporozoites, tachyzoites, etc.) of e.g., ► [Apicomplexa](#) being involved in host cell attachment and in induction of host cell invasion. Such adhesins include micronemal erythrocyte binding antigens (EBA-family – EBA 140, 175, 181) as well as the rhoptry-localized reticulocyte-binding homologs (Rh family) of ► [Plasmodium](#) species (Rh1, Rh2a, 2b, Rh4 and Rh5). These different proteins are characteristic for the effects of ► [micronemes](#) and ► [rhoptries](#) of the motile stages of apicomplexan groups of parasites such as members of the genera ► [Eimeria](#), ► [Isospora](#), ► [Cystoisospora](#), *Toxoplasma*, ► [Sarcocystis](#), ► [Plasmodium](#), etc.

Adhesion Molecules

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Several molecules that mediate adhesion e.g., of ► [Entamoeba histolytica](#) to mucus of the host cell are:

1. 260 kDa *N*-acetyl-D-galactosamine inhibitable lectin
2. *N*-acetylglucosamine inhibitable lectin of 220 kDa
3. 112 kDa surface adhesion

Hook-like appearing copulation organ of male bed bugs, which is used to penetrate the outer ventral surface of females and to inject sperms into the ► [Ribaga](#) organ or even directly into the body cavity.

Aedes albopictus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This so-called Asian tiger mosquito (Fig. 1) is one of the vectors of the chikungunya and dengue

Aedes albopictus*,*Fig. 1** Light micrograph of a female *Aedes albopictus****Aedes albopictus*, Fig. 2** Worldwide distribution of *Aedes (Stegomyia) albopictus* (blue = countries with native populations; red = countries with non-native (established)

populations; yellow = countries with sporadic occurrence – not established populations (from Becker et al. 2012))

fevers – has started successfully a passive spread across the globe in recent times of total globalization of goods via ships and airplanes. Originally it was native to South-East Asia, but it is now found in the USA, Latin America, Africa, Europe, and on islands in the Pacific and Indian Oceans. Thus many countries have established special surveillance programs fearing that these mosquitoes might be involved in outbreaks of dengue fever in their new homelands (Fig. 2).

Aegyptianella pullorum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Anaplasma pullorum; the agents of disease are transmitted by fowl ticks (e.g., *Argas persicus* and related species.

Aelurostrongylus abstrusus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *ailouros* = cat, *strongylos* = cylindric; Latin: *abstrusus* = hidden; English = cat lungworm.

Life Cycle

A. abstrusus is a metastrongylid nematode, which infects the lungs of cats and other felids (e.g., Amur cat = *Felis bengalensis euphilurus* and Eurasian lynx = *Lynx lynx*). This parasite has been found in numerous cases in Europe, in Australia, and in North and South America as well as occasionally in Asia and Africa. Global prevalences in free roaming cats occur between 1 % in Spain and 50 % in Albania. The females reach a length of 14 mm, the males are 6–7 mm long. The cats excrete the 400 µm long larvae 1 via feces or nasal discharge. Intermediate hosts (e.g., nudibranchial snails, e.g., *Arion* species) ingest these larvae with their food. Inside these hosts, the larva 2 and 3 are developed. The latter is finally infectious for cats; however, they probably become mostly infected when they feed paratenic hosts like mice or birds, which previously had ingested infected snails. After 6 weeks, the adult stage is reached in the lung.

Symptoms of Disease

In lungs, the worms are enclosed within nodules of up to 1 cm in diameter. While slight infections remain symptomless, heavy infections may lead to cough, tachypnea, bleedings, or even may end fatal.

Diagnosis

The larvae 1 can be isolated from feces by help of the ► [Baermann](#) funnel system.

Treatment

Fenbendazole (20–50 mg/kg bodyweight) daily for 5–15 days as well as fenbendazole paste (Panacur®) administrated at 50 mg/kg bodyweight over three consecutive days have been proven to offer full curative effects.

Aequorin

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes a fluorescent protein that is used to detect calcium in vivo. It originates from the jellyfish *Aequorea victoria*.

Aerobacter

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Bacterial genus, the member of which are participating in the symptoms of the disease of demodicidosis (see ► [Demodex](#) mites).

Aerogen

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *aer* = air; *gignesthai* = derive from.

This term describes the transmission of agents of disease by air.

Aeromonas hirudinis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Species of gram negative bacteria, which are transmitted by ► [leeches](#) (Hirudinea).

Aeropyls

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Pores in the operculum of the eggs of ► [lice](#).

Aesculap Stick

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: Aesculapius; Greek: Asklepios: God of medicine, son of god Apollon and goddess Coronas. The stick which is surrounded by a snake is a symbol for the healing power of physicians.

Aethina Fumida

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Parasitic beetle which spends its whole life in bee stocks feeding honey as well as larvae of bees.

Aetiology

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Greek-derived term for the science of the origin of diseases.

AFC

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Caused by the ► [ASF virus](#) (ungrouped), African swine fever is an acute, contagious disease leading to high mortality in domestic pigs. It is maintained in wild pigs, particularly warthogs (*Phacochoerus* spp.), and in the tick *Ornithodoros porcinus*. It has been reported that infected male *O. porcinus* can infect uninfected females during mating. Warthogs are usually not severely affected, but it can be considered one of the most serious diseases of domestic swine, where it can be transmitted by contact alone and has caused severe economic losses after introduction into European countries.

African Trypanosomiasis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Unstained wet blood preparations, chancre fluid, CSF, or lymph node aspirate can be used for the

demonstration of motile trypanosomes. Giemsa-stained slides should also be prepared from the same material. With native blood samples it will be usually possible to demonstrate trypanosomes of *Trypanosoma brucei rhodesiense*, but less frequently those of *T. b. gambiense* since parasitemia is usually much lower with this parasite. Here, concentration techniques may be successful, such as blood centrifugation and subsequent examination of the buffy coat, also in the form of the quantitative buffy coat technique (QBC). Mini anion-exchange and centrifugation are other useful methods.

Antibody detection methods proved to be too insensitive or unspecific for a reliable diagnosis of African trypanosomiasis.

Afropamus balanoides

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Intermediate host (snail) of ► [Paragonimus uterobilateralis](#).

Agamermis decaudata

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Species of free-living nematodes, the larvae of which are parasitic in grasshoppers and thus become transported to other biotopes.

Agamodistomum suis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Diplostomal trematode species of pigs, which are thought to represent mesocercariae of ► *Alaria allata*. They are also described as ► *Duncker's muscle fluke*.

Agamogony

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Asexual reproduction (e.g., ► *schizogony* and ► *sporogony* in ► *Coccidia*).

Agamostomum

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Old name of mesocercariae of the digenetic trematode species ► *Alaria allata*, (► *Diplostomatidae*) as ► *paratenic host pig*, which had apparently fed one of the regular second intermediate hosts (frog larvae). Another name for such an infection is *Duncker's muscle cone*.

Agents of Disease

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

► *Prions*, viruses, bacteria, fungi, parasites (plants, animals).

Age-Related Prevalence

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Prevalence rate of parasites in a host is mostly dependent on its age, i.e., it increases with the time of exposition, e.g., in ► *Clonorchis sinensis* and hookworms. In soil-transmitted nematodes, however, the prevalence is high beginning after the first year of host's life. In other parasites (e.g., in coccidians), infections occur mainly in the first weeks of life.

Aggregata eberthi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: *aggregatus* = accumulated; Eberth = name of describer.

This species belongs to the family of Klossiidae in the ► *Coccidia* (► *Apicomplexa*, ► *Sporozoa*) of the subregnum Protozoa (= unicellular organisms). The peculiarity of the species of the Klossiidae is that their male and

Aggregata eberthi, Fig. 1 Life cycle of *Aggregata eberthi* in its hosts. 1–5 After oral uptake of sporocysts (19) by the crab (*Portunus* sp.) the sporozoites (1) are set free, leave the intestine, and enter cells of the connective tissues surrounding the gut; inside a ►parasitophorous vacuole (PV) schizonts (3) produce 7–9 μ m long, motile merozoites (4, 5). 6–11 As soon as the crab has been eaten by the cuttlefish *Sepia officinalis* (final host), the merozoites penetrate through the gut wall into cells of the submucosa. There they grow into macrogamonts (6, 7) or microgamonts (9). The latter produce numerous biflagellate microgametes (10, 11), which are about 30 μ m in

length and have an additional recurrent flagellum. 12 Fertilization of the ►macrogamete (200 μ m in diameter). 13 ►Zygote, surrounded by a very smooth ►oocyst wall. 14–19 During ►sporogony many globular sporocysts (16) are formed inside the smooth-walled oocyst. Each ►sporocyst produces three sporozoites: large numbers of sporocysts are found within the feces of the cuttlefish (or within necrotic pieces of its gut). Crabs are again infected when ingesting such sporocysts. F flagellum of microgamete, HC host cell, MG microgamont, N nucleus, NH nucleus of the host cell, PV parasitophorous vacuole

female gamonts (= stages before formation of gametes) become closely attached to each other before the formation of the gametes is proceeded. In contrast to “classic” coccidians, such as *Eimeria* or *Isoospora* species, where the oocysts contain four (► [Eimeria](#)) or two (► [Isoospora](#)) sporocysts, in *Aggregata eberthi* many of them are found in the smooth-walled oocysts (Fig. 1). *Aggregata* species occur in molluscs (e.g., *A. eberthi* in the cuttlefish *Sepia officinalis* or *A. octopiana* in the common *Octopus vulgaris* and in predators (e.g., brachyceran crustaceans). While the sexual development is proceeded in the final host (here cuttlefish), the schizogony runs inside the intermediate host (here the decapod crab *Portunus* sp.) (Fig. 1). At first, the *Aggregata* had been considered as ► [gregarines](#) by Lieberkühn (1854) and were later transferred to the coccidians (Schneider 1875).

Alaria alata

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

General Information

1. **Name:** Latin: *ala* = wing; *alaris* = belonging to the wing.
2. **Geographic distribution/epidemiology:** Worldwide, especially in regions with wild dogs, foxes, wolves, and martens. Prevalences of *Alaria* species in dogs in the USA (*A. canis*, *A. americana*) and in foxes in Germany are up to 30 %.

Alaria alata, Fig. 1 Life cycle of *Alaria canis* (*A. americana*). 1 The adults (2.5–4.2 mm long) live in the anterior third of the small intestine of the final hosts (canids). 2 The operculate eggs are unembryonated when laid. 3 Larvae (miracidia) hatch in about 2 weeks after reaching water. 4 Miracidia swim actively and enter several species of helisomid snail (first intermediate host), inside which mother ► **sporocyst** and daughter sporocyst are produced. The latter gives rise to ► **cercariae**. 5 The furcocercous cercariae leave the snail during daylight hours and swim to the water surface, where they hang upside down. 6 If tadpoles (as intermediate hosts of the second type) pass by, the cercariae penetrate the skin. In about 2 weeks, the cercariae become transformed into mesocercariae (6.1, 6.2 show surface view). 7–9 2 weeks after infection, the mesocercariae are infectious for a series of paratenic hosts or directly for the final host (canids) if

this host ingests an infected tadpole (or an adult frog after its ► **metamorphosis**). Inside the ► **paratenic host**, the mesocercariae are accumulated (8) in various tissues without further development. Large numbers of mesocercariae are very pathogenic for their hosts. If humans become accidentally infected, severe damage or death may occur. Mesocercariae which have reached the intestine of the final host penetrate into the body cavity and pass through the diaphragm into the lungs by the end of 2–3 weeks. Here, they transform into ► **diplostomula** (metacercariae) in about 5–6 weeks. The diplostomula migrate up the trachea and are finally swallowed. Inside the intestine, they mature in about 4 weeks and cause severe enteritis. FB forebody, FT forked tail, GP genital pore, HB hindbody, HF holdfast organ, IN intestine, OP operculum, OS oral sucker, OV ovary, PH pharynx, TE testis, UT uterus with eggs, VI vitellarium, VS ventral sucker

3. **Morphology/life cycle:** The life cycle is diagrammatically represented in Fig. 1. It runs similarly in the different species: *A. canis* (syn. *A. americana*), *A. mustelae* (marten), and *A. marcianae* (cats). The hermaphroditic adult worms, which belong to the digenetic trematodes of the family Diplostomatidae,

reach a size of 2.5–6 mm × 0.5–2 mm and live in the intestine mainly of wild canids. Their brownish eggs, which measure 98–125 μm × 62–81 μm, possess an operculum, but do not contain a miracidium, when they are excreted in feces. The latter develops inside the egg outside of its host, when the

***Alaria alata*,**

Fig. 2 Lightmicroscopic picture of an adult worm of *Alaria* sp.

egg reached water. Two intermediate host types become involved as can be seen in Fig. 1.

4. **Symptoms of disease:** Depending on the number of parasites in a host, an infection may run symptomless, whereas heavy infections may lead to catarrhal enteritis or even as a consequence to death of the final host. Since pigs and wild boars as well as humans may become infected, too, they also may suffer from symptoms of disease. They become paratenic hosts in case they ingest mesocercariae of *A. alata* within tissues of one of the second intermediate hosts (Fig. 1).
5. **Diagnosis:** Coproscopic investigation after use of ► **SAFC**, ► **MIFC**, or flotation techniques for concentration of eggs within feces is the method of choice.
6. **Infection:** Final hosts (i.e., canids) become infested when ingesting infected intermediate hosts of the second type (Fig. 1). In the USA, raccoons were also found to act as intermediate hosts (Fig. 2).
7. **Prophylaxis:** Domestic dogs or other canids should not be fed with raw meat from wild animals.
8. **Incubation period:** 4–6 weeks.
9. **Prepatent period:** 19–21 days.
10. **Patency:** Years.
11. **Treatment:** Praziquantel (5 mg/kg bodyweight, 1 × oral application).

Alaria alata and Related Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin *ala* = wing; *alaris* = belonging to the wing.

Geographic Distribution/Epidemiology

Worldwide, especially in regions with wild dogs, foxes, wolves, and martens. Prevalences of *Alaria* species in dogs in the USA (*A. canis*, *A. americana*) and in foxes in Germany up to 30 %.

Morphology/Life Cycle

The life cycle is diagrammatically represented in Fig. 1. It runs similarly in the different species: *A. canis* (syn. *A. americana*), *A. mustelae* (marten), and *A. marcianae* (cats). The

hermaphroditic adult worms, which belong to the digenetic trematodes of the family Diplostomatidae, reach a size of 2.5–6 × 0.5–2 mm and live in the intestine mainly of wild canids. Their brownish eggs, which measure 98–125 μm × 62–81 μm, possess

***Alaria alata* and Related Species, Fig. 1** Life cycle of *Alaria canis* (*A. americana*). (1) The adults (2.5–4.2 mm long) live in the anterior third of the small intestine of the final hosts (canids). (2) The operculate eggs are unembryonated when laid. (3) Larvae (miracidia) hatch in about 2 weeks after reaching water. (4) Miracidia swim actively and enter several species of helisomid snail (first intermediate host), inside which mother ► **sporocyst** and daughter sporocyst are produced. The latter give rise to ► **cercariae**. (5) The furcocercous cercariae leave the snail during daylight hours and swim to the water surface, where they hang upside down. (6) If tadpoles (as intermediate hosts of the second type) pass by, the cercariae penetrate the skin. In about 2 weeks, the cercariae become transformed into mesocercariae (6.1 and 6.2 show surface view). (7–9) Two weeks after infection, the mesocercariae are infectious for a series of paratenic hosts or directly for the final host (canids) if

this host ingests an infected tadpole (or an adult frog after its ► **metamorphosis**). Inside the ► **paratenic host**, the mesocercariae are accumulated (8) in various tissues without further development. Large numbers of mesocercariae are very pathogenic for their hosts. If humans become accidentally infected, severe damage or death may occur. Mesocercariae which have reached the intestine of the final host penetrate into the body cavity and pass through the diaphragm into the lungs by the end of 2–3 weeks. Here, they transform into ► **diplostomulae** (metacercariae) in about 5–6 weeks. The diplostomulae migrate up the trachea and are finally swallowed. Inside the intestine they mature in about 4 weeks and cause severe enteritis. **FB** forebody, **FT** forked tail, **GP** genital pore, **HB** hindbody, **HF** holdfast organ, **IN** intestine, **OP** ► **operculum**, **OS** oral sucker, **OV** ovary, **PH** pharynx, **TE** ► **testis**, **UT** uterus with eggs, **VI** ► **vitellarium**, **VS** ventral sucker

an operculum but do not contain a miracidium, when they are excreted in feces. The latter develops inside the egg outside of its host, when the egg reached water. Two intermediate host types become involved as can be seen in Fig. 1.

Symptoms of Disease

Depending on the number of parasites in a host, an infection may run symptomless, whereas heavy infections may lead to catarrhalic enteritis or even as consequence to death of the final host. Since pigs and wild boars as well as humans may become infected, they also may suffer from symptoms of disease. They become paratenic hosts in case they ingest mesocercariae of *A. alata* within tissues of one of the second intermediate hosts (Fig. 1).

Diagnosis

Coprosopic investigation after the use of SAFC, MIFC, or flotation techniques for concentration of eggs within feces is the method of choice.

Infection

Final hosts (i.e., canids) become infested when ingesting infected intermediate hosts of the second type (Fig. 1). In the USA also raccoons were found to act as intermediate hosts.

Prophylaxis

Domestic dogs or other canids should not be fed with raw meat from wild animals.

Incubation Period

Four to six weeks.

Prepatent Period

Nineteen to twenty-one days.

Patency

Years.

Treatment

Praziquantel (5 mg/kg bodyweight, 1 × oral application).

Badly healing skin lesion: a symptom of cutaneous leishmaniasis, named after Aleppo, a town in the Middle East (Syria).

Alimentary System Diseases, Animals

Gastrointestinal parasites affect their hosts, both directly and indirectly, through a wide variety of mechanisms. The diseases are associated mainly with ► *anorexia*, loss of productivity, and ► *diarrhoea* (► *Clinical Pathology*, Animals). The characteristic changes in blood constituents are ► *hypoalbuminaemia* and ► *anaemia* – for parasites inducing loss of blood. Abomasal parasitism is associated with characteristic increases in the concentration of plasma pepsinogen and liver parasitism with increases in the levels of liver enzymes.

The lesions caused by important parasites of domestic animals have been described many times and will not be dealt with in detail. Briefly,

lesions may be almost negligible, e.g., in *Moniezia* infections in ruminants. They may also be confined to the point of attachment of the parasite, as with the tapeworm *Anoplocephala* in horses or the acantocaphalan *Macrocanthorynchus hirudinaceus* in the pig. At the other extreme, lesions caused by some parasites may cover entire parts of the gastrointestinal tract such as during infections with ► *Ostertagia* in the abomasum, ► *Strongyloides* in the small intestine, or ► *Trichuris* in the large bowel. Finally, the liver fluke ► *Fasciola hepatica* causes hepatic necrosis and haemorrhages during migration, and erosions of the biliary mucosa when it reaches the bile duct.

It is not always possible to establish a link between the severity of the lesions and either the impaired physiology of an organ, or the secondary manifestations of disease, such as anorexia, ► productivity loss, ► diarrhoea, or haematological changes. For example, lambs infected with ► *Haemonchus contortus* and given a low-protein diet show more severe clinical signs of ► weight loss, anaemia, and loss of appetite than others given a normal diet, despite similar levels of blood loss. Dietary protein supplementation may not, however, be successful in animals with concurrent abomasal and intestinal infections in which compensatory digestion and an increase in intestinal absorption of nutrients depend upon the integrity of the latter organ. On the other hand, larval challenge of immune animals may cause impaired production despite low parasite burdens. It is important to consider these nutritional and immunological factors during any field observations. They may well account for some of the conflicting reports on the effect of parasitism. A genetically determined variation in the susceptibility of cattle and sheep to certain ► helminth infections has also been demonstrated. Inherited resistance, as assessed by faecal egg output, worm burdens, or clinical symptoms of disease, has been described, e.g., in sheep or cattle infected with *Ostertagia* spp., *Haemonchus contortus*, *Cooperia* spp. and ► *Trichostrongylus*

spp. Finally, the interaction between parasitism and the physiological condition of the ewe is well documented: the postparturient rise in worm egg output is attributed to a loss of resistance associated with late pregnancy and lactation. The common clinical signs and pathology of the parasitic diseases of the alimentary tract are summarized in: Alimentary System Diseases, Ruminants, Alimentary System Diseases, Horses, Alimentary System Diseases, Swine, Alimentary System Diseases, Carnivores.

Therapy and other measurements are presented in the chapters on control and disease control and under ► Drugs.

Alimentary System Diseases, Carnivores

The common clinical signs and pathology of the parasitic diseases of the gastrointestinal tract of carnivores are summarized in Table 1.

Protozoal Enteritis

Coccidiosis (*Coccidiosis, animals*) and cryptosporidiosis have been reported in dogs and cats. *Giardia* spp. occurs in dogs and cats, and giardiasis may represent an important problem in these hosts. It causes ► anorexia, depression, and a mild recurring ► diarrhoea consisting of soft, light-coloured stools with a characteristic “oatmeal” texture, frequently containing mucus. Growth retardation and cachexia may occur. The mechanism by which giardial malabsorption and ► diarrhoea occurs is unclear. Epithelial damage, increased turnover of epithelial cells, villous shortening, and disaccharidase deficiency have all been reported as manifestations of giardiasis. ► *Entamoeba histolytica* is the cause of ► *entamoebiasis* in humans and among domestic animals. The disease which occurs rarely in dogs is characterized by diarrhoea.

Alimentary System Diseases, Carnivores, Table. 1 Gastrointestinal parasitic diseases of carnivores (according to Vercruysse and De Bont)

^bProbably identical with ► [Neospora caninum](#)

Occurrence of signs: ± rare, + common, ++ very common

Gastrointestinal Helminthosis

Oesophagus

► [Spirocerca lupi](#), the oesophageal worm, is a parasite usually associated with the formation of ► [nodules](#) in the oesophageal wall. Occasionally, however, it may be found in gastric nodules in cats. Most infected dogs are not clinically

affected and the infection is only detected at necropsy. Signs of oesophageal involvement include anorexia, ► [vomiting](#), dysphagia, and bloodstained regurgitus. There is a strong evidence of a causal relationship between *Spirocerca* and oesophageal fibrosarcomas or osteosarcomas. Ventral spondylitis of caudal thoracic vertebrae is also observed, the cause might

be migrating worms inducing periosteal irritation.

Stomach

The presence of parasites in the stomach of dogs and cats does not commonly produce signs, except in severe infestations. The overall incidence of these parasites is low. Several ► **nematodes** have been identified in the stomachs of dogs, cats, and wild carnivora: *Cylicospirura*, *Cyathospirura*, *Spirura*, *Physaloptera* spp., ► *Gnathostoma spinigerum*, and *Ollulanus tricusps*. Only the latter three parasites are likely to cause signs of gastric parasitism. *Physaloptera* spp. inhabit the stomach and proximal duodenum of many carnivores and may be a cause of vomiting and chronic gastritis. Regurgitation may occur, presumably because of the oesophagitis induced by vomiting. Adults of *G. spinigerum* are found in groups up to 10 in cysts within the gastric mucosa of cats and dogs. The cysts may be 2 cm in diameter, and communicate with the gastric lumen by small openings. Gnathostomosis has been associated with illness and death. Symptoms include anophagia, occasional vomiting, ► **abdominal pain**, and loss of weight.

Ollulanus tricusps inhabits the stomach of cats. Although most infections are asymptomatic, *O. tricusps* should be included in the differential diagnosis for vomiting in cats, especially when vomiting is postprandial.

Small Intestine

Several ► **trematodes** cause infections in carnivores. ► *Schistosoma japonicum* live within the mesenteric and hepatic portal veins of dogs (Schistosomiasis, Animals Ruminants).

Many genera of trematodes (*Apophallus*, *Heterophyes*, *Alaria*, *Nanophyetus*, and others) are parasitic in dogs and cats throughout the world, but they are only rarely of any clinical consequence. ► *Nanophyetus salmincola* is important as a vector of the highly pathogenic *Neorickettsia helminthoeca*, the cause of “► **salmon poisoning**” in dogs, a disease with a high mortality rate.

Dogs may be parasitized by a great number of ► **cestodes**. Some common species are *Taenia*

hydatigena, *T. pisiformis*, *T. ovis*, *Taenia multiceps*, *T. serialis*, ► *Dipylidium caninum*, ► *Echinococcus* spp., ► *Mesocestoides* spp., and *Spirometra* spp. Two species occur frequently in cats: *Taenia taeniaeformis* and *Dipylidium caninum*.

In most cases there are few, if any, clinical symptoms. Infections have been associated with diarrhoea and failure to thrive, but concomitant gastrointestinal nematode parasitism may often be of greater significance. The passage through the rectum and anus of the gravid segments of *Taenia* and *Dipylidium caninum* produces irritation in dogs, but not in cats. The proglottides passing through the rectum, or lodging in the anal glands, frequently cause the dog to scoot.

Strongyloidosis in dogs is caused by ► *Strongyloides stercoralis*. Though not common, infection in young animals may have severe consequences. There is enteritis with erosion of the mucosa of the small intestine and haemorrhages. Bloody diarrhoea occurs in heavy infections. ► **Dehydration** develops rapidly, and death may occur.

There are four hookworm species that commonly affect dogs and cats. ► *Ancylostoma caninum* and *A. tubaeforme* are the most pathogenic species of dogs and cats, respectively. *A. braziliense* is another hookworm parasite of dogs and cats and is not very pathogenic. *Uncinaria stenocephala* is mainly a hookworm of dogs; in cats it is much less common. *U. stenocephala* is the least pathogenic of the ► **hookworms** that affect dogs and cats. With *A. caninum*, disease results from blood loss into the bowel which leads to iron deficiency, ► **anaemia** (hypochromic, microcytic). In ► **chronic infections** there is emaciation, poor appetite, and pica and the animals are frail. There is some diarrhoea and the faeces are dark and sometimes blood-streaked.

With respect to ascarid infections ► *Toxocara canis* is by far the commonest roundworm of dogs. It is not highly pathogenic and the effects of infection are often overstated. During larval migration various tissues (liver, lung, heart, kidney) may show granulomatous lesions. The pulmonary phase may be lethal in pups infected

heavily before birth; death occurring within a week after birth. This is the most severe effect of *T. canis* infection. Once the worms have become adults in the small intestine the only clinical signs are those of pot-bellied abdomen, light diarrhoea, and failure to thrive. Adult worms are often passed in the faeces or vomited. The other ascarid of the dog, and rarely the cat, *Toxascaris leonina*, is non-migratory and of little pathological importance.

► *Toxocara cati*, the ascarid of cats, is endemic in all countries. As for infections with *T. canis*, many cases remain asymptomatic.

The Acanthocephalan *Onicola canis* occurs in the small intestine of wild carnivores and occasionally of dogs and cats. The lesions are the same as those described for *Macrocanthorynchus hirudinaceus* in swine (Alimentary System Diseases, Swine), although clinical manifestations are rare.

Caecum, Colon, Rectum, Anus

The most important species are *T. vulpis* in dogs, and *T. campanula* and *T. serrata* in cats. ► *Trichuris* is highly prevalent in all parts of the world but rarely causes clinical signs. Heavy infections associated with severe and often haemorrhagic typhlitis or typhlocolitis has been reported in dogs. Clinical manifestations include failure to thrive, ► [weight loss](#), abdominal pain, diarrhoea, dehydration, and terminal anaemia. In severe cases the faeces may be speckled with fresh blood. The lesions are caused by the adult worms boring tunnels into the mucosa of the large intestine.

Liver

The commonest parasite of the liver of cats, and less frequently in dogs, is *Opisthorchis felinus*. The signs of infection are emaciation, jaundice, and ascites.

Capillaria hepatica occurs only rarely in the liver of cats and dogs, and infection remains inapparent.

Therapy

► [Chemotherapy](#), ► [Drugs](#).

Alimentary System Diseases, Horses

The common clinical signs and pathology of the parasitic diseases of the gastrointestinal tract of horses are summarized in Table 1.

Protozoal Enteritis

The only ► *Eimeria* sp. occurring in horses, *Eimeria leuckarti* (► [Coccidiosis](#), Animals) has been only sporadically reported to cause ► [diarrhoea](#) in young horses. *Cryptosporidium* has been reported in all domestic animals (Cryptosporidiosis, Animals) including horses. In horses, symptoms have been particularly observed in animals with inherited or acquired immunodeficiency. *Giardia* spp. are usually non-pathogenic inhabitants of the small intestine of horses. However, they may cause diseases under certain circumstances, such as in animals which are immunocompromised, malnourished, or very young.

Gastrointestinal Infections

Stomach

► *Trichostrongylus axei* occurs in the stomach of horses. The worm is rarely a pathogen on its own, most infections are chronic and mild. However, *T. axei* induces typical lesions in horses. The condition has been described as a *gastritis chronica hyperplastica et erosiva circumscripta* for the main lesion is a pad- or cushion-like thickening in the glandular part of the stomach.

The most common parasites of the equine stomach are larvae of botflies of the genus ► *Gasterophilus*. The most common species which pass to the stomach and settle on the gastric mucosa are *G. intestinalis* followed by *G. haemorrhoidalis*. Despite the dramatic

^aClinical signs and pathology: 1 ► Loss in performance, ► Weight Loss, 2 ► Anorexia, 3 Diarrhoea, 4 ► Constipation, 5 ► Abdominal Pain, 6 ► Hypoalbuminaemia, 7 Others

Occurrence of signs: ± rare, + common, ++ very common

appearance of a heavy bot infestation, its true veterinary significance is unclear. The parasites may produce significant gastric lesions, but primarily in the non-glandular part of the stomach which plays little role in digestion. This is possibly the reason why the vast majority of infections remain asymptomatic. Yawning and unsatisfactory performance are described as common signs. Erratic movements of the larvae into the abdomen (with or without peritonitis) are described.

The spiruroid ► nematodes *Habronema majus*, *H. muscae*, and *Draschia megastoma* are also parasitic in the stomach of equidae. ► *Habronema* species lie on the mucosal surface while *Draschia* burrows in the submucosa to produce large,

tumour-like ► nodules. *D. megastoma* is therefore the most pathogenic of the ► stomach worms, although clinical signs remain inapparent in most cases. The parasite is often incorrectly blamed for the disease and death of the host because of the very impressive character of the lesions it produces.

Small Intestine

The ► cestodes found in the small intestine are ► *Anoplocephala magna* and *Paranoplocephala mamillana*. In most cases they induce few, if any, clinical symptoms. The only ► *Strongyloides* spp. in horses is *Strongyloides westeri* (Strongyloidosis, Animals/Ruminants). Clinical outbreaks principally affect young suckling

foals. Signs include ► [anorexia](#), loss of weight, coughing, ► [diarrhoea](#) (rarely haemorrhagic), ► [dehydration](#), and slight to moderate ► [anaemia](#). Severe infections may be fatal. The ascarid ► *Parascaris equorum* is a common parasite in young horses. Both the parasitic migration through the lungs and the intestinal phase of the life cycle may be associated with clinical signs. Symptoms include lethargy, loss of appetite, coughing, nasal discharge, and decreased weight gain. In the rare severe infections the intestinal phase may cause impaction, rupture, peritonitis, intussusception, and formation of abscesses.

Caecum, Colon, Rectum, Anus

Members of the trematode genus *Gastrodiscus* may be found in the colon of horses and swine, but they are of little clinical significance. However, the immature trematode has been reported to cause a severe and hyperacute, possibly fatal colitis in horses.

The cestode *Anoplocephala perfoliata* is commonly found in the distal small intestine, caecum, and proximal large intestine. A significant number of the parasites often accumulates at the ileocaecal junction and may produce marked lesions there. *A. perfoliata* is a significant risk factor for spasmodic colic and ileal impaction colic in the horse. The risk of spasmodic colic increases with infection intensity.

Members of the Strongylidae are abundant and common nematode parasites of the caecum and colon in Equidae. There are 55 species of strongyles, with fewer than 20 commonly found in horses, usually as mixed infections. Therefore, the clinical signs can be considered to be caused by all the worm species collectively. Specific clinical signs may arise due to the larval stages of the *Strongylus* spp. These are described in the section on the cardiovascular system. Adult large strongyles are inhabitants of the large intestine. They feed by attaching to the glandular epithelium and drawing a plug of mucosa into the buccal capsule. Incidental damage to blood vessels in the plug results in bleeding. Some, as seen with clusters of *Triodontophorus* spp., cause deep ulcers. The damage thus caused results in the formation of crater-like ulcers which may extend deep into

the gut wall. These lesions are believed to be the cause of anaemia, failure to thrive, and poor performance. The colitis and typhlitis do not often lead to diarrhoea. The adults of the Cyathostominae feed mainly on intestinal contents and are of little pathogenic significance. *Cyathostoma*-associated clinical disease is attributed to the synchronous emergence of large numbers of previously inhibited third- and fourth-stage larvae from the large intestinal wall, resulting in physical disruption of the mucosa and typhlitis/colitis. Animals sometimes develop a fatal syndrome (winter cyathostominosis) characterized by sudden onset of diarrhoea, mild colic signs, failure to thrive or cachexia, and ► [hypoalbuminaemia](#). Emaciation possibly results from the anorexia, the reduction of absorptive function, and the loss of protein through the disrupted intestine. A reduced level of ileocaecocolic motility was recorded in ponies experimentally infected with a mixture of strongyles, predominantly cyathostomes. It was argued that this would reduce propulsion of ingesta, and cause loss of appetite and weight. Additional mechanisms which may contribute to the occurrence of cyathostome-associated colic include intestinal mucosal ► [oedema](#) and/or vasoconstriction induced by the local production of vasoactive substances in response to the presence of cyathostome mucosal stages.

The only oxyurid of importance is *Oxyuris equi*, the large pinworm of horses. It is never regarded as a serious pathogen. The chief feature of oxyuriasis in equines is the ► [anal pruritus](#) produced by the egg-laying females. The irritation caused by the anal pruritus produces restlessness and improper feeding. The animal rubs the base of its tail against any suitable object, causing the hairs to break off and the tail to acquire an ungroomed “rat-tailed” appearance.

Liver

A variety of cestodes, nematodes, and ► [trematodes](#) produce inflammation of the liver and bile ducts, but they are of minor importance in horses. *Parascaris equorum*, *Strongylus equinus*, and

S. edentatus migrate through the liver, but only *S. edentatus* has been associated with transient colic. *Echinococcus granulosus* is commonly found in the liver. Although they may involve a large amount of tissue, hydatid infections appear to be well tolerated. ► *Fasciola hepatica* is occasionally found in the equine liver. Heavy infections are rare and are usually discovered only during post-mortem examination.

Abdominal Cavity

Most of the parasites found in the peritoneal cavity have their final habitat elsewhere and passage through the peritoneum occurs in the normal course of migration, or by accident. Parasites normally migrating through the peritoneal cavity are the immature *Fasciola hepatica*, *Strongylus edentatus*, and *Strongylus equinus*. They can cause acute and chronic peritonitis.

Examples of accidental passages are those of *Parascaris equorum* and *Gasterophilus*, which enter the cavity through intestinal or gastric perforations.

Therapy

- Chemotherapy, Nematocidal Drugs,
- Cestodocidal Drugs.

Alimentary System Diseases, Ruminants

The common clinical signs and pathology of the parasitic diseases of the gastrointestinal tract of ruminants are summarized in Table 1.

Protozoal Enteritis

Coccidiosis (► Coccidiosis, Animals) and Cryptosporidiosis (Cryptosporidiosis, Animals) are

very common diseases in young ruminants. *Cryptosporidium parvum* is frequently observed in calves and lambs of 1–4 weeks of age. Watery diarrhoea, sometimes with blood, is very typical and animals may dehydrate and show retarded growth. Morbidity is high but mortality is low in most cases. However, lethal cryptosporidiosis has been reported, possibly related to strain-specific virulence. *C. parvum* is not host specific and may also infect humans where severe disease may occur in immune-compromised individuals. Other *Cryptosporidium* spp. have been described in ruminants; however, these appear to be of no or very limited clinical significance.

Many *Eimeria* spp. have been identified in ruminants; however, only few are of clinical importance. Depending on the infection pressure *Eimeria bovis* or *E. zuernii* may induce subclinical disease or moderate to severe, sometimes haemorrhagic, diarrhoea in calves. Lesions are mainly found in the large intestine. Watery diarrhoea related to infection of the small intestine with *E. alabamensis* has been repeatedly reported in grazing calves. In sheep, *E. ovinoidalis*, *E. bakuensis*, and *E. ahsata* are considered particularly pathogenic; in goats, *E. ninakohlyakimovae* and *E. arloingi* are the most pathogenic species. Dehydration and hypoproteinaemia are typical signs of coccidiosis; fever and anorexia may be observed in severe cases. Disease symptoms are generally seen before oocysts are shed which makes specific diagnosis difficult. Coccidiosis-related mortality is variable but usually low. Recovering calves may show retarded growth. Cryptosporidiosis and coccidiosis are self-limiting diseases and generally disappear after 2–14 days. Drugs for therapy are available (toltrazuril, diclazuril), but effective control depends on strategic measures (improvement of hygiene, disinfection, and metaphylactic/prophylactic treatment). *Giardia* spp. are usually non-pathogenic inhabitants of the intestine of cattle, sheep, and goats. However, they may cause diseases under certain circumstances, such as in animals which are immunocompromised, malnourished, or very young.

Occurrence of signs: ± rare, + common, ++ very common

Gastrointestinal Helminthosis

Abomasum

Various infections of the abomasum have been reported of which ► *Ostertagiosis* is probably the most important disease in grazing sheep and cattle in temperate climatic zones throughout the world. It causes subclinical losses of production and disease. The clinical disease is characterized by ► diarrhoea, ► weight loss, decreased production, rough hair coats, partial ► anorexia, mild ► anaemia, ► hypoalbuminaemia, ► dehydration, and in some cases death. ► *Ostertagia ostertagi* in cattle and *O. (Teledorsagia) circumcincta* in sheep and goats are the most important species.

► *Haemonchosis* is a common and severe disease of the ruminant abomasum in many parts of the world. ► *Haemonchus contortus* infects mainly sheep and goats, while *H. placei* occurs mainly in cattle. The pathogenesis of *Haemonchus* infection is the results of anaemia and hypoproteinaemia caused by the bloodsucking activity of the parasite.

► *Trichostrongylus axei* lives in the abomasum of cattle, sheep, and goats. In ruminants, *T. axei* infections are usually part of a mixed abomasal helminthosis and its effects cannot be dissociated from those of other worm species. The worm is rarely a pathogen on its own, as most infections

are mild. Animals experimentally infected with large numbers of *T. axei* show a decrease of blood albumin, haemoconcentration, and a rise in serum pepsinogen. The clinical signs include diarrhoea, anorexia, progressive emaciation, listlessness, and weakness.

The pathogenesis of *M. digitatus* resembles that of *H. placei*. A drop in haematocrit to less than 20 % has been reported in cattle infected with more than 1000 worms.

Small Intestine

Paramphistome infections may cause significant intestinal problems in ruminants (► *Paramphistomosis*). The adult worms live in the rumen, but the pathological effects of infection are caused by the immature stages within the small intestine. The most pathogenic species are thought to be *Paramphistomum microbothrium*, *P. ichikawai*, ► *P. cervi*, *Cotylophoron cotylophoron*, and various species of *Gastrothylax*, *Fishoederius*, and *Calicophoron* (► *Digenea*).

Schistosomes live within the mesenteric and hepatic portal veins of ruminants. Although ► *Schistosoma* infections in ruminants are highly prevalent in certain regions, the general level of infestation is often too low to cause clinical disease or losses in productivity. Levels sufficiently high to cause outbreaks of clinical schistosomosis

do occur occasionally and infestation becomes manifest either as an intestinal syndrome which is usually self-limiting, or as a chronic hepatic syndrome, which is usually progressive (Schistosomiasis, Animals). The intestinal syndrome is caused by the deposition of large numbers of eggs in the intestinal wall and usually follows a heavy infestation in a susceptible animal, i.e., an animal in which the capacity of the host to suppress the egg laying of the parasite has not been stimulated by previous infestations. This has been reported among cattle, sheep, and goats infected with either *S. bovis* or by *S. matthei*. As the faecal egg counts rise sharply with the onset of egg production the animal develops a mucoid and then haemorrhagic diarrhoea, accompanied by anorexia, loss of condition, general weakness and dullness, roughness of coat, hypoalbuminaemia, and paleness of mucous membranes. Death may occur 1 or 2 months after the onset of clinical signs. In most cases, the animal makes a spontaneous but slow recovery. The primary cause of the diarrhoea is the passage of large numbers of eggs through the wall of the intestine. The anaemia is usually due to an increased rate of red cell removal from the circulation; while haemodilution and the inability to mount a sufficiently effective erythropoietic response are of secondary importance. The underlying cause of the hypoalbuminaemia is hypercatabolism of albumin due to substantial loss of protein in the gastrointestinal tract.

In ruminants the more common and widely distributed intestinal ► **Cestodes** are ► *Moniezia expansa*, *M. benedeni*, *Thyzanietzia* (*Helicometra*) *giardi*, *Stilesia globipunctata*, and ► *Avitellina* spp. These ► **tapeworms** live in the middle third of the small intestine. They are generally of minor pathological importance and only produce harmful effects on the host in rare circumstances. The host-parasite relationship is so well adjusted that there is a surprising absence of apparent pathogenicity, even in such heavy infestations that the passage of intestinal contents may be impeded by the worms and, in most cases there are few, if any, clinical symptoms. Infections have been associated with diarrhoea and ill thriving, but concomitant gastrointestinal nematode parasitism

may often be of greater significance. In sheep *S. globipunctata* infections may cause signs of enteritis. The pathogenesis of this parasite is associated with the immature stages, which enter the mucosa of the intestine and induce the formation of ► **nodules**.

Several nematode species cause severe gastrointestinal diseases such as Strongyloidosis, Trichostrongylosis, ► **Cooperiosis**, and ► **Nematodirosis**. Hookworm infections are caused by the two ancylostomatids occurring in cattle *Bunostomum phlebotomum*, and the little known *Agriostomum vryburgi*. Two species occur in sheep and goats: *Bunostomum trigonocephalum* and *Gaigeria pachyscelis*. Apart from the little damage to the mucosa of the small intestine caused by the bites, the entire pathogenesis of these worms is attributable to bloodsucking, which begins when larvae enter the adult stage. In addition to the withdrawal of great quantities of blood by the parasites, the feeding sites continue to bleed for several minutes after the worms have moved to another area. The signs are those of a rapid loss of blood: pale mucosae, hydraemia, sometimes ► **oedema**, lassitude, and loss of weight. The faeces are often diarrhoeic and contain bloody mucus, or may be tarry in character.

The anaemia that develops is first normocytic and normochromic, but later becomes microcytic hypochromic as the animal becomes iron deficient. Other pathological changes recorded are hypoproteinaemia, hypocalcaemia, hyperglycaemia, and ► **eosinophilia**. The lowered plasma protein levels may be caused by both a compensatory replacement of haemoglobin at the expense of circulating plasma proteins and the loss of blood taken by the parasites. The non-specific loss of body fluid by leakage would account for the lowered plasma calcium values; the calcium associated with plasma albumin being lost with the protein.

Toxocara vitulorum, the pathogenic ascarid of large ruminants, is most commonly found in buffalo and cattle calves of less than 4 months of age. Infection occurs through ingestion of larvae with the milk from the mother. The clinical signs in calves relate primarily to the bulk of parasites in

the small intestine, which impedes the passage of ingesta and impairs the assimilation of food. The clinical signs include anorexia, diarrhoea or ► constipation, dehydration, steatorrhoea, ► abdominal pain, and a butyric odour of the breath.

Caecum, Colon, Rectum, Anus

► Trichuris spp., the whipworms, inhabit the caecum and occasionally the colon of ruminants (Trichuriasis, Animals). Members of the genus ► Oesophagostomum infect cattle, sheep, and goats (► Oesophagostomosis).

► Chabertia ovina is found in the colon of sheep, cattle, goats, and deer throughout the world. Infections are usually light in intensity, and outbreaks of clinical disease are sporadic. Disease in sheep is associated with the presence of fifth stage and adult worms in the colon. Affected animals have a severe diarrhoea, sometimes blackened by blood. Ill thriving has been reported. The adults penetrate the muscularis mucosae and take a plug of mucosa into the buccal capsule; minor haemorrhage may be related to physical trauma to the mucosa but this blood loss is insufficient to induce anaemia in natural infections. More significant is the loss of plasma protein from the mucosa, which may cause hypoalbuminaemia and weight loss.

Liver

The common clinical signs and pathology of the parasitic diseases of the liver of ruminants are summarized in Table 2.

A variety of ► cestodes, ► nematodes, and ► trematodes produce inflammation of the liver and the bile ducts. Some of the parasites produce hepatic lesions in the course of their natural or accidental migration to their final habitat in the guts. The traumatic lesions produced by such larvae rarely cause disease, and are mostly found incidentally during post-mortem examination. Very heavy infections in sheep with the oncospheres of Cysticercus tenuicollis may induce severe haemorrhagic migration tracts in

Alimentary System Diseases, Ruminants, Table 2 Parasitic diseases of the liver (ruminants) (according to Vercruysse and De Bont)

Parasite	Clinical signs
Dicrocoelium spp.	Loss of condition
Fasciola hepatica, F. gigantica	Acute (sheep): anorexia, distended abdomen pain, death. Mild: hypoalbuminaemia, hyperglobulinaemia eosinophilia, light anaemia. Chronic: loss of appetite, pale mucosae, oedema, productivity loss, Hypoalbuminaemia, anaemia, SGOT, γ-GT rise
Fascioloides magna	Sheep: weakness, death
Gigantocotyle explanatum	Decreased production, enlargement of bile ducts, inflammatory reactions
Schistosoma spp.	Loss of condition, diarrhoea

the liver. Animals are weak, show abdominal pain, and have an enlarged, often palpable liver. Death may occur.

The most important parasites of the liver are those which have their final habitat in this organ.

Trematodes

A variety of trematodes are very important parasites of the liver of animals. They belong to the families Fasciolidae (► Fasciola hepatica, ► F. gigantica, and ► Fascioloides magna), Dicrocoeliidae (► Dicrocoelium dendriticum, D. hospes), and Paramphistomatidae (Gigantocotyle explanatum).

Fasciola hepatica, the common liver fluke, is the most widespread and important of the group. F. gigantica occurs in the tropics. It occurs mainly in sheep and cattle, but a patent infection can develop in horses, pigs, wild animals, and in humans. The pathogenesis of fasciolosis is attributable in part to the invasive stages in the liver and in part to the blood feeding by the adults in the bile ducts. The process in all hosts shows close similarities, but considerable variation in severity occurs (Fasciolosis, Animals).

The host range of Fascioloides magna includes cattle, bison, sheep, goat, and horse but it is only recognized as a pathogen of sheep. In sheep this parasite wanders continuously in the liver and

causes extensive parenchymal destruction. Even a few ► [flukes](#) may kill a sheep. *Dicrocoelium*, as with many ► [liver flukes](#), has a wide host range including both sheep and cattle. The pathological changes in the liver are less severe than those seen in *F. hepatica* infection (Fasciolosis, Animals) and even in heavy infections there may be no clinical signs.

A chronic hepatic syndrome has been described in cattle infected with *Schistosoma mattheei*. This syndrome is less common than the intestinal syndrome (see above). It is characterized by progressive hepatic fibrosis and may be manifested clinically as chronic hepatic insufficiency, with loss of condition, or as acute terminal hepatic failure, which often provokes nervous signs as ataxia or mania. The established condition is invariably fatal. The syndrome is of immunological origin and apparently depends on the ability of the ox to limit the infestations by destruction of adult parasites. It is probably initiated by an immunological reaction in the hepatic portal veins to antigen released by dead or dying worms in the portal system. The lesion is analogous to Symmer's pipestem fibrosis in man.

Gygentocotyle explanatum occurs in the bile ducts of ruminants in Asia. Heavy infections induce inflammatory reactions, with enlargement of the bile ducts. Decreased production has been reported.

Cestodes

Thysanosoma actinoides and *Stilesia hepatica* are parasites of the bile ducts of ruminants. They are both practically non-pathogenic.

Abdominal Cavity

Most of the parasites found in the peritoneal cavity have their final habitat elsewhere and passage through the peritoneum occurs in the normal course of migration, or by accident. The only parasite of importance is *Fasciola hepatica* as it can cause acute and chronic peritonitis.

Other parasites, such as the commonly seen *Setaria*, use the peritoneal cavity as their final

habitat. All members of this genus live as well-adjusted parasites in their normal host and do not cause peritoneal lesions.

Therapy

- [Cestodocidal Drugs](#), Nematocidal Drugs.

Alimentary System Diseases, Swine

The common clinical signs and pathology of the parasitic diseases of the gastrointestinal tract of swine are summarized in Table 1.

Protozoal Enteritis

Coccidiosis (► [Coccidiosis, Animals](#)) and Cryptosporidiosis (► [Cryptosporidiosis, Animals](#)) have been reported in pigs. Although it is possible to experimentally induce clinical cryptosporidiosis in piglets this pathogen appears to be of little significance under natural conditions. Pigs serve as hosts for a number of coccidia species of the genus *Eimeria*. Oocysts of *Eimeria* are frequently found in adult pigs, particularly sows, but are only rarely associated with clinical disease or reduced performance. In contrast, *Isospora suis* is now widely accepted as a major cause of enteritis in suckling piglets. Prevalence is very high in young piglets and generally peaks in the second or third week after birth. Even moderate infection levels can induce diarrhoea in suckling pigs. Due to the short prepatency of around 5 days, rapid sporulation in the environment and high reproductive potential *I. suis* spreads rapidly within a litter and across farrowing crates. Faeces is of pasty to watery consistency, gray to yellow, and has a typical odour. Although mortality is low the economic loss may be considerable due to impairment of piglet performance which may continue after weaning in recovered animals. ► [Balantidium coli](#) occurs in the large bowel in pigs and sometimes other mammals. It is normally

present as a commensal in the lumen but is capable of invasion of tissues injured by other diseases (e.g., ► *Trichuris* infection, see below).

Gastrointestinal Helminthosis

Stomach

There are several helminths that possibly live in the stomach of swine. In contrast to ruminants, ► *Trichostrongylus axei* occurs rarely in pigs (Trichostrongylosis). ► *Hyoststrongylus rubidus* is the most important parasite of the stomach of swine but very rare under conventional keeping conditions. This trichostrongylid nematode produces lesions resembling those caused by ► *Ostertagia* in ruminants, but with less severe consequences. Listlessness, thirst, ► **anorexia**, ► **anaemia**, ► **diarrhoea**, and reduced weight gains may occur. Under field conditions hyoststrongylosis is associated with the “thin-sow syndrome.” Parasite or host strain differences may account for some of the variations recorded in the literature regarding the effects of

experimental *H. rubidus* infections on swine health and performance.

Gnathostoma hispidum live deep in the gastric mucosa where they may cause severe ulceration. Migrating larvae may be found in the liver where they leave necrotic tracks. *Physocephalus sexalatus* and *Ascarops strongylina* may be found free in the lumen or partly embedded in the mucosa. *Simonsia paradoxa* female worms form palpable ► **nodules** in mucosal crypts. Clinical signs of acute or chronic gastritis, and occasional ulceration have only been observed in the rare heavy infections.

Small Intestine

The trematode ► *Schistosoma japonicum* lives within the mesenteric and hepatic portal veins of pigs (► **Schistosomiasis**, **Animals**).

Strongyloidosis caused by *Strongyloides ransomi* occurs in swine. Clinical outbreaks principally affect piglets. Signs include anorexia, loss of weight, diarrhoea (rarely haemorrhagic), ► **dehydration**, and slight to moderate anaemia. Severe infections may be fatal.

► **Hookworms** of the genus ► *Globocephalus* appear to be of little significance in swine (► **Alimentary System Diseases, Ruminants**).

Ascaris suum is a very common parasite of pigs. Its importance is related both to the sometimes very significant lesions caused by larvae during migration through the liver and lungs, and to the effects of adult worms in the small intestine. In the liver, the travelling larva causes intralobular necrosis and a granulation reaction known as “milk spots.” However, these lesions are not associated with symptoms. In the ordinary moderate infections, adults have no defined pathogenesis. In heavy infection, there is experimental evidence of reduction in growth rate, diarrhoea, and ill thriving. Intestinal obstruction is rare.

The Acanthocephalan *Macrocanthorynchus hirudinaceus* is the thorny-headed worm of swine, which infects the small intestine. The worm causes trauma at the site of attachment with its thorny ► **proboscis**. The proboscis may penetrate as far as the serous coat, and nodules of up to 1 cm in diameter may be visible on the serosal surface of the gut. They occasionally perforate, causing peritonitis. Severely infected pigs may suffer ill thriving and anaemia. The latter is probably related to the loss of plasma protein and to the haemorrhages from numerous ulcerative lesions. The pigs often show signs of acute ► **abdominal pain** during these infections.

Caecum, Colon, Rectum, Anus

The ► **whipworm** *Trichuris suis* inhabits the caecum of pigs. Heavy infections associated with severe and often haemorrhagic typhilitis or typhlocolitis has been reported. Clinical manifestations include anorexia, dysentery, dehydration, ► **weight loss**, and terminal anaemia. In severe cases the faeces may be markedly haemorrhagic or even all blood. The lesions are caused by the adult worms boring tunnels into the mucosa of the large intestine. Penetration of the mucosa by the parasites produce nodules in the intestinal wall (► **Alimentary System Diseases, Carnivores**). It has been shown that concurrent infections with *T. suis* enhances the ability of opportunistic bacteria to multiply and cause disease and pathology.

► **Oesophagostomosis** has been reported in pigs. The two common species found in pigs are *O. quadrispinulatum* and *O. dentatum*. Although the parasites themselves are generally highly prevalent, clinical ► **oesophagostomosis** is not common in pigs. The “thin-sow-syndrome” has been associated with oesophagostomosis. At necropsy distinct nodules caused by the histotropic larvae are a common observation.

Liver

The most important parasitic condition affecting the liver of pigs is the “milk spots” caused by the passage of ascarid larvae (see supra). The pathogenesis of ► *Stephanurus dentatus* infections (► **Urinary System Diseases, Animals**) is primarily related to the damage caused by the larvae during their migration through the liver. Hepatitis cysticercosa, resulting from the migration of *Cysticercus tenuicollis*, may be rarely observed in pigs (► **Alimentary System Diseases, Ruminants**).

► *Fasciola hepatica* has been found in pigs, but infections are very rare. Hepatic schistosomosis occur in swine infected with *S. japonicum*. The lesions resemble those observed in cattle (► **Alimentary System Diseases, Ruminants**).

The opisthorchid ► **flukes** (*Opisthorchis felineus*, ► *Clonorchis sinensis*) are normally parasitic in the bile ducts of carnivores. However, they may also occur in swine and humans. The signs of heavy infection are emaciation, jaundice, and ascites.

Abdominal Cavity

Most of the parasites found in the peritoneal cavity have their final habitat elsewhere and passage through the peritoneum occurs in the normal course of migration, or by accident. Parasites normally migrating through the peritoneal cavity are the immature *Fasciola hepatica* and *Stephanurus dentatus*. Both can cause acute and chronic peritonitis.

Alphitobius diaperinus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This dark brown-blackish beetle, which reaches a length of 4.5 mm up to 7 mm, has its origin in

tropical regions of East Africa. However, due to ongoing globalization this species is now found worldwide everywhere in grain storage system and in many of the huge rearing facilities of chickens, turkeys, goats, etc. Due to this living within bird food, this species became a vector of a broad spectrum of agents of diseases of farmed birds.

(a) Viruses:

- Virus of bursitis, virus of Newcastle disease (ND), virus of infectious bronchitis (IB), corona virus of poultry enteritis, etc.

(b) Bacteria:

- *Salmonella* species, *Campylobacter* spp., *Escherichia coli*, *Staphylococcus aureus*, and strains of *Streptococcus* sp.

(c) Parasites:

- Cestodes (like *Hymenolepis minutissima*, *Choanotaenia infundibulum*, *Raillietina* sp., *Cotugnia* sp.)
- Protozoa (like *Eimeria* species).

Except for tapeworms, where these beetles act as true intermediate hosts, most of the above cited agents of diseases are transmitted mechanically. However, since these beetles occur often in extreme numbers in stored bird food, they must be considered as very important vectors of agents of diseases.

Genus of the former class Ciliates. Specimens of several species are firmly attached at the skin of

General Information

Genus of hard ► [ticks](#), which comprises about 100 species, the most important of which are found in Africa south of the Sahara and in the New World in tropical and subtropical humid regions (not in Europe). Important species are the Bont tick *A. hebraeum* (nicely colored;

A

Amblyomma, Fig. 1 Light micrograph (left) of a female of *A. hebraeum*; diagrammatic representation (right) of a male and female of *Amblyomma* sp

Fig. 1) in South Africa, *A. variegatum* (Tropical bont tick) in East Central Africa, *A. pomposum* (Highland bont tick) in western Central Africa, *A. americanum* (Lone star tick) in the USA, Eastern Coast until Central Texas, *A. maculatum* (Gulf Coast tick) in the southern states of the USA, and *A. cajennense* (Cayenne tick) from Texas to Argentina. All *Amblyomma* spp. involve three hosts. Their sucking always induces painful skin lesions, necroses, itching, ulcers, granulomas (e.g., *A. cajennense* in horses). Also humans are attacked by larvae and nymphs when walking on cattle meadows. Loss of weight is enormous, if large amounts of ticks suck at cattle. *A. hebraeum* needs at least 171 days for one generation, it produces nearly 20,000 eggs per female and each stage may starve for more than 6 months. Thus they are absolute competitive ectoparasites. As vectors they are known to transmit stages of *Ehrlichia* spp., *Rickettsia rickettsii*, *Cowdria ruminantium*, *Coxiella burneti*, *Hepatozoon americanum* (*A. americanum*), *Theileria mutans* (*A. variegatum*, *A. hebraeum*), *Cytauzoon felis* = *Theileria* (*A. variabilis*).

Disease

Amblyospora

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *amblys* = weak; *sporos* = see, spore.

Amblyospora, Fig. 1 Life cycle of *Amblyospora* species using different *Culex* stages (A, B, C, E, F) and copepods (D) as hosts. 1 Inside adult female ► mosquitoes (A) diplocaryotic ► spores are formed (dens wall) which are transovarially transmitted to the eggs (B) and to the developing larvae (C) of the insect. 2, 3 Inside the larvae diplocaryotic meronts (DC, M) reproduce and finally give rise to unicaryotic (N) meiospores eight within a sporophorous vesicle. During this process most larvae die, thus setting free the meiospores which are ingested

by another host, i.e., by a copepod (D). 4 Within the copepod, finally uninucleate spores are formed from meronts. 5 When such uninucleate spores are swallowed by larvae of mosquitoes, various generations of diplocaryotic meronts are formed and persist in the pupae and adults of the insects. In the adult ► mosquitoes, finally new diplocaryotic spores are produced (1). DC ► diplocaryon, M meront, MS meiospore, N nucleus, SPV sporophorous vacuole

The species of the family Amblyosporidae (phylum Microsporidia) are common parasites of mosquitoes and use also copepod crustaceans as hosts. Their life cycles include sexual and asexual reproduction phases and end in the production of multiple spore types, which

allow vertical (transovarial) and horizontal transmission. The development in an intermediate host is obligatory. Up to now, more than 150 species of microsporidians have been described from species of more than ten mosquito genera.

As an example Fig. 1 shows the life cycle of *Amblyospora albifasciati* in the *Aedes albifasciatus* mosquito and in the copepod (*Mesocyclops annulatus*).

Amebic Liver Abscess (ALA)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the effects of the invasion of ► [Entamoeba histolytica](#) stages into the human liver. It was shown that the occurrence of this clinical symptom is age and sex depending. While infection rates among women are similar, ALA manifests predominantly in adult men.

American Trypanosomiasis (Chagas Disease)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

In the acute stage of ► [Chagas Disease](#), the direct examination of anticoagulated blood or its buffy coat will usually reveal the presence of motile trypanosomes. Giemsa-stained thin or thick blood films are useful for confirmation. Direct visualization of trypanosomes is much more difficult in the chronic stage of the disease, where culture in NNN medium, blood inoculation into mice, or xenodiagnosis with uninfected reduviid bugs are used to propagate the causative parasite which then becomes detectable by microscopic examination. Where appropriate facilities are available, PCR may be useful for detecting *T. cruzi* in blood.

For epidemiological or individual screening, the indirect fluorescent antibody test (IFAT)

proved to be highly sensitive. However, cross-reactivity with *Leishmania* spp. co-endemic with *T. cruzi* in various areas of Latin America limits the usefulness of the IFAT.

Ametabolic Development

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

In contrast to hemi- and holometabolic development of insects, which have a pupal stage or not, ametabolic (wingless) insects grow up just by repeated molts and thus look similar during their whole life cycle.

Amidines

Heinz Mehlhorn

Düsseldorf, Germany

General Information

1. **Name:** Greek: *amido* = enlarged, noncentral; *stoma* = mouth; Latin: *anser* = goose.

2. **Geographic distribution/epidemiology:** Worldwide among farmed and free-living geese.
3. **Morphology/life cycle:** The adults of *A. anseris* are characterized by a mouth capsule with three sharp teeth. Males reach a length of 10–17 mm and possess a bursa copulatrix with three lobes and two similarly long spicula (~200 µm) plus a gubernaculum. Females reach a length of 12–24 mm. Both sexes appear reddish-yellowish and live in the muscular stomach below the keratinoid layer of the stomach of geese and some other waterfowls. The eggs measure 80–110 µm × 50–80 µm and contain many blastomeres when excreted. Related species are *A. acutum* in the muscular stomach of geese and ducks (worldwide) and *Epomidiostomum uncinatum* (with a reduced mouth capsule in the muscular stomach of ducks and geese (worldwide)). The larva 3 develops inside the eggs when excreted on the soil. At temperatures of ~20 °C, it takes about 3 weeks until this infectious stage is reached. Then, the sheathed larva 3 hatches from the egg shell and crawls up to the tips of grass. If geese ingest these contaminated plants, the larvae start often from the smooth walled stomach, a migration via blood to lung, and reach finally again the space of the mucous and the keratinoid layer. If eggs or larva 3 had fallen into water, the larva 3 is also able to penetrate the skin of swimming birds, and after a body migration, they reach their final sites, too.
4. **Symptoms of disease (amidostomiasis):** Symptoms are mainly found in very young birds, which then show severe symptoms of anemia and a delayed growth with respectively considerable losses of weight. Animals are hit by diarrheas and weakness. Severe cases with more than 1,000 worms may lead to death after occurrence of heavy inflammation reactions in the stomach. However, light infections may remain symptomless.
5. **Diagnosis:** Microscopic determination of the eggs (80–110 × 50–80 µm in size) by the help of ► [flotation](#) concentration.

6. **Infection:** Oral uptake of eggs containing the larva 3 or after penetration of larva 3 swimming in water, where they may survive up to 1 month.
7. **Prophylaxis:** Quick removal of feces from stables.
8. **Incubation period:** First symptoms of disease occur already after 2 weeks.
9. **Prepatent period:** 15–33 days in young animals, up to 7 weeks in older geese.
10. **Patency:** Young animals, about 160–180 days; older animals, mostly only 3–4 months.
11. **Therapy:** The anthelmintic compounds flubendazole, mebendazole, and levamisole are highly effective and registered in many countries.

Name

Greek: *amido* = enlarged, non-central;
stoma = mouth; Latin: *anser* = goose.

Geographic Distribution/Epidemiology

Worldwide among farmed and free living geese.

Morphology/Life Cycle

The adults of *A. anseris* are characterized by a mouth capsule with three sharp teeth. Males reach a length of 10–17 mm and possess a bursa copulatrix with three lobes and two similarly long spicula (~200 µm) plus a gubernaculum. Females reach a length of 12–24 mm. Both sexes appear reddish-yellowish and live in the muscular stomach below the keratinoid layer of the stomach of geese and some other waterfowls. The eggs measure 80–110 µm × 50–80 µm and contain many blastomeres when excreted. Related species are *A. acutum* in the muscle stomach of geese and ducks (worldwide) and *Epidomostomum uncinatum* (with a reduced mouth capsule in the muscular stomach of ducks and geese (worldwide)). The larva 3 develops inside the eggs when excreted on soil. At temperatures of ~20 °C it takes about 3 weeks until this infectious stage is reached. Then the sheathed larva 3 hatches from the egg shell and crawls up to the tips of grass. If geese ingest these contaminated plants, the larvae start often from the smooth-walled stomach a migration via blood to lung and reach finally again the space of the mucous and the keratinoid layer. If eggs or larva 3 had been fallen into water, the larva 3 is also able to penetrate the skin of swimming birds and after a body migration they reach their final sites, too.

Symptoms of Disease (Amidostomiasis)

Symptoms are mainly found in very young birds, which then show severe symptoms of anemia and a delayed growth respectively considerable losses of weight. Animals are hit by diarrheas and weakness. Severe cases with more than 1000 worms may lead to death after occurrence of heavy inflammation reactions in the stomach. However, light infections may remain symptomless.

Diagnosis

Microscopical determination of the eggs (80–110 × 50–80 µm in size) by help of ► [flotation](#) concentration.

Infection

Oral uptake of eggs containing the larva 3 or after penetration of larva 3 swimming in water, where they may survive up to 1 month.

Prophylaxis

Quick removal of feces from stables.

Incubation Period

First symptoms of disease occur already after 2 weeks.

Prepatent Period

15–33 days in young animals, up to 7 weeks in older geese

Patency

Young animals: about 160–180 days, older animals mostly only 3–4 months.

Therapy

The anthelmintic compounds flubendazole, mebendazole, and levamisole are highly effective and registered in many countries.

Amino Acids

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Like all other organisms, parasitic protozoa and helminths require the basic set of 20 amino acids for their protein synthesis, formation of other biomolecules, and, to a lesser extent, for energy production. The majority of these amino acids are essential for the parasite and have to be obtained from the diet or from exogenous proteins. Ingested proteins are hydrolyzed within specialized organelles (lysosomes, lysosome-like organelles, and other specialized vacuoles) into their constituent amino acids by the concerted action of specific proteinases and peptidases. In nematodes and trematodes, protein digestion is accomplished in the gut lumen. The amino acid metabolism of parasites resembles that of higher animals, but there are differences regarding the properties of the enzymes involved, the relative importance of the various pathways, and the occurrence of a variety of unusual metabolic routes. The unique properties of amino acid metabolism found in protozoan parasites are often determined by secondary gene loss and lateral gene transfer, primarily from bacterial lineages.

Biosyntheses and Interconversions

The carbon skeletons of glycine, alanine, serine, aspartate, and cysteine are derived primarily from glycolytic or Krebs cycle intermediates, while the α-amino groups are usually furnished by transamination reactions from glutamate. The latter amino

Amino Acids, Fig. 1 Interrelationships between the arginine dihydrolase pathway, methionine recycling and biosynthetic routes for polyamines and trypanothione in protozoan parasites. The arginine dihydrolase pathway is unique to *Giardia* and trichomonads and is used for energy generation, polyamine biosynthesis, and amino acid nitrogen elimination. Certain protozoa utilize a mechanism for methionine recycling during polyamine biosynthesis that is modified from that present in other eukaryotes. In this pathway, the intermediate MTA is converted in a two-step reaction to MTR-1-P involving the microbial enzymes MTA

nucleosidase and MTR kinase. In other eukaryotes, MTA is converted to MTR-1-P in one step by a phosphorylase. Trypanothione biosynthesis occurs only in trypanosomatids. 1, Arginine deiminase; 2, arginase; 3, ornithine carbamoyltransferase; 4, carbamoylphosphate kinase; 5, ornithine decarboxylase; 6, spermidine synthase; 7, 5'-methylthioadenosine (MTA) nucleosidase; 8, 5-methylthioribose (MTR) kinase; 9, trypanothione synthase. AdoMet, S-adenosylmethionine; dcAdoMet, decarboxylated AdoMet; MTA, methylthioadenosine; MTR, methylthioribose; MTR-1-P, methylthioribose-1-phosphate

acid is formed from ammonia and the Krebs cycle intermediate, α -ketoglutarate. Other amino acids are produced by amino acid interconversions, a capacity in which parasites can differ greatly from their hosts. An unusual metabolic feature of some protozoa is the conversion of arginine to ornithine,

ammonia, and CO_2 by a route called arginine dihydrolase (ADH) pathway (Fig. 1). In eukaryotic organisms, this pathway has been reported to be present only in *Giardia*, trichomonads, and a green alga, in which it serves as an energy generating source, ornithine production for further

Amino Acids, Fig. 2 The proline biosynthetic pathway in trematodes. 1, Arginase; 2, ornithine aminotransferase; 3, spontaneous reaction; 4, pyrroline 5-carboxylate reductase

biosynthesis of polyamines, and the removal of amino acid nitrogen (Fig. 1). In *Trichomonas vaginalis* one of the enzymes of the ADH pathway, arginine deiminase, has been localized to the hydrogenosomes, whereas all other enzymes of this route are present in the cytosol. Other unusual routes of amino acid interconversions can occur during catabolism. Examples are procyclic *Trypanosoma brucei*, *T. cruzi* epimastigotes, and *Leishmania* promastigotes, which possess high rates of proline oxidation resulting in the formation of succinate mainly (energy metabolism). Like in other organisms, cysteine can be synthesized in most parasites from methionine, with the exception of *Giardia*, which is absolutely dependent on an exogenous supply of this amino acid for survival and growth. In common with bacteria and higher plants, anaerobic protozoa synthesize cysteine from serine and inorganic sulfide, involving a two-step reaction via either *O*-acetylserine or *O*-phosphoserine. Examples for more profound differences in sulfur compound metabolism between parasites and their mammalian hosts are the exclusively bacterial enzyme methionine γ -lyase catabolizing methionine and cystathionine in certain anaerobic protozoa, and the novel type of cystathionine β -synthases of trichomonads and nematodes involved in cysteine synthesis from homocysteine as well as in cysteine degradation. *Giardia*, *Entamoeba histolytica*, and *Plasmodium falciparum* possess a unique pathway for methionine recycling from methylthioadenosine produced from decarboxylated S-adenosyl-methionine (Fig. 1). This process serves to conserve the essential amino acid for polyamine and other biosyntheses and involves enzymes, which are otherwise only found in prokaryotes. A unique feature of several apicomplexan species is their ability to synthesize chorismate (shikimate pathway), the pivotal precursor in bacteria, fungi, and plants for the biosynthesis of aromatic amino acids,

ubiquinone, and folic acid. However, no evidence was yet found for a role of chorismate in the synthesis of aromatic compounds in apicomplexan parasites. The shikimate pathway is present in plasmodia and in cyst-forming coccidians but is missing in *Babesia* and *Theileria*.

The large quantities of proline produced by *Fasciola hepatica*, schistosomes, and other trematodes correlate with an extremely active proline pathway in these helminths. In contrast to higher organisms, in which glutamate serves as the precursor for proline synthesis, the liver fluke and schistosomes use host-derived arginine as preferred substrate for the production of this amino acid (Fig. 2). The enzymes involved in the proline pathway of helminths are several times more active than in mammalian tissues. This, together with the absence of proline oxidase, aids in explaining the excessive levels of proline produced by certain helminths that have been implicated in the pathogenesis of trematode infections, including bile duct hyperplasia in fasciolosis and fibrosis in schistosomiasis.

Catabolism

Like higher animals, the first step in amino acid catabolism in parasites is often the removal of the α -amino nitrogen mediated primarily by transamination and deamination reactions. The ammonia arising from these reactions constitutes a major portion of the total excretory nitrogen in endoparasites. While in most terrestrial vertebrates the α -amino nitrogen is finally converted into urea by the urea cycle, the presence of this pathway in parasites appears doubtful. The small amounts of urea produced by helminths possibly derive from the cleavage of dietary arginine. In addition to ammonia, many parasites excrete a substantial amount of their amino nitrogen in the form of

amino acids, primarily as alanine and proline. This metabolic strategy is also common in free-living protozoa and invertebrates but is unusual in higher animals, where oxidative degradation with associated energy production is the preferred strategy for amino acid breakdown. Larval and adult helminths were also found to excrete amines as end products of amino acid metabolism. The formation of these compounds, which includes various alkylamines and ethanolamine, appears to be catalyzed by unusual and as yet unknown enzymatic mechanisms. Certain amino acids can serve as important energy sources for parasites, including proline for insect-stage trypanosomatids, arginine for anaerobic protozoa, and glutamine for filarial parasites (see above). In all these processes, substrate oxidation is incomplete and results, besides some CO₂, in the formation of partially oxidized end products.

Precursor Function

Except in being the building blocks for protein synthesis, the capability of parasites to use amino acids as precursors for synthetic purposes is rather limited. An example is the absence of the pathways for the de novo synthesis of purines in parasites for which glycine and aspartate are major precursors. Although amino acid-derived neurotransmitters and neurohormones are widely distributed among helminths, little is known about their synthesis in these organisms. Most of the neurophysiologically active substances found in worm tissues, such as histamine, serotonin (5-hydroxytryptamine), and catecholamines may be primarily of host origin.

Classification

Order of ► **Protozoa** (new phylum Amoebozoa).

General Information

Among the Sarcodina (► **Rhizopoda**), only the amoebae are of parasitological interest. Amoebae are characterized by the presence of an endo- and ectocyttoplasm, and by their locomotion and reeding as consequences of the formation of ► **pseudopodia** (► **Trichomonadida**/Fig. 2). These family-specific formations originate from the outward flow of ► **cytoplasm** and push the ► **cell**

membrane ahead in the direction of flow; amoebic stages cannot swim, but creep around the substratum or the intestine (or vessels) of a parasitized host. Some of the amoebae, however, may become flagellated during their life cycles.

Most members of the order Amoebida are free-living, although some are facultative (Table 1, page 74) or accidental (Figs. 1, 2, 3, 4, 5, 6, 7, and 8) pathogens; others live regularly as parasites. Reproduction of the parasitic species occurs by asexual binary or multiple division (► **Cell Multiplication**); sexual stages have not been described. ► **Transmission** occurs by oral uptake of fresh ► **trophozoites** or by ingestion of cysts (if present), the wall of which is excreted by the

Amoebapora A

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This is a protein of *Entamoeba histolytica*, which may initiate openings in membranes of endothelial cells of the host. Its structure belongs to the archetypes of saposin-like proteins. Similar proteins have been found in porcine and human cytotoxic lymphocytes and have been described as “natural killer lysine” and “granulolysin,” respectively.

Amoebapore

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

A polypeptid that is excreted by ► [trophozoites](#) of ► [Entamoeba histolytica](#). It comes in contact with host cell membranes and initiates the formation of ion channels. This introduces the lysis of these cells and thus opens the entry of the amoeba into the intestinal wall. Recently, it was also found in *Acanthamoeba* and *Naegleria*.

Synonyms

Amoebic dysentery; *Entamoeba histolytica* infection

Distribution

See Fig. 1

Pathology

Infectious disease caused by the amoeba ► *Entamoeba histolytica* which may be commensal in the gut for long periods of time, or it may invade the mucosa soon after infection. The dose of infection, the strain of ► amoebae, the nutritional state of the patient, and the nature of the intestinal flora are likely to be determinants of the development of disease. Axenic animals with an intestine

free of bacteria do not appear to develop invasive amoebic infection. Some strains of amoebae are more pathogenic and appear to share isoenzyme or genomic patterns, described as zymodemes or schizodemes. Although multiple pathogenic mechanisms of *E. histolytica* have been described, none have been definitively linked with pathogenicity. The amoebic ► trophozoites are best demonstrated with the periodic acid Schiff (PAS) technique (► Pathology, Fig. 4c, d) because most trophozoites contain glycogen. Also, their ► cytoplasm stains more distinctly with Giemsa or eosin than the smaller macrophages. They adhere to the intestinal epithelium and generally invade in areas where the intestinal mucus appears depleted. The amoebae fan out in the lamina propria and submucosa, giving rise to “flask-shaped” ulcers (► Pathology, Fig. 4a). The histolytic nature of the amoebae is suggested by the lysis of the surrounding cells, seen light microscopically by lysis of the nuclei and by ultrastructural changes in the cytoplasm. However, the clear space around individual amoebae is largely a fixation artifact. Neutrophils are attracted by the amoebae and are degranulated and lysed (► Pathology, Fig. 4b). This release of neutrophil granules may contribute to tissue destruction. The absence of neutrophils around the ulcers is notable. The absence of fecal leukocytes with positive results of a guaiac test for blood is a useful diagnostic finding. However,

Amoebiasis, Fig. 1 Distribution map of amoebic dysentery

eosinophilic leukocytes are often seen histologically, and ► [Charcot-Leyden crystals](#) may be found in the stool. The magna-stages phagocytose red blood cells and cell debris which distinguishes *E. histolytica* from nonpathogenic amoebae. Intestinal ulcers may extend through the muscularis (► [Pathology](#), Fig. 4c) and lead to intestinal perforations. This complication is made more likely by the administration of anti-inflammatory corticosteroids which can occur if an erroneous diagnosis of inflammatory bowel disease has been made. However, ► [AIDS](#) patients do not appear to be especially susceptible to recrudescences.

The amoebae often invade the veins in the submucosa of the gut (► [Pathology](#), Fig. 21b) and are transported to the liver and rarely other organs (lung, brain, skin), where they may set up foci of infection. Liver abscesses may reach a size of several centimeters. They usually develop in the right side according to the laminar flow of the portal vein drainage from the colon. The amoebae colonize, lyse, and digest the liver cells, giving rise first to amoebic hepatitis (► [Pathology](#), Fig. 4d). Only when the focus of destroyed liver ► [parenchyma](#) is too large for the lysed debris to be absorbed into the lymphatic and venous circulation will an ► [abscess](#) result. The center of the abscess is formed by brownish, semiliquid fluid which is said to resemble “anchovy paste.” A liver abscess may extend through the diaphragm into pleura and lung with the abscess material being coughed up. Older abscesses are surrounded by fibrinous chronic inflammatory-reaction products or by fibrosis. The amoebic trophozoites are found in the periphery of the abscess between the liver cells, best identified in PAS-stained sections (► [Pathology](#), Fig. 4d). The delicate nuclei of the trophozoites are shown with hematoxylin and eosin, but they stain less intensely than the nuclei of macrophages from which they need to be distinguished. Amoebic cysts are found only in the stools and not in the tissues. Invasive amoebiasis is enhanced by immunosuppression of whatever cause, e.g., by corticosteroid administration, as mentioned above, and in patients with AIDS. *Entamoeba histolytica* infections also occur in extraintestinal sites, penile infections following

anal intercourse, infections of the cervix uteri, and the buccal mucosa.

Immune Responses

Intestinal amoebiasis is characterized by fulminant diarrhea and intestinal hemorrhage. The associated disruption of the intestinal epithelium allows hematogenous dissemination of the parasite leading to granuloma formation most commonly found in the liver. Survival of amoebic trophozoites may be favored by a transient immunosuppression associated with hepatic infections. The downregulation of the host's immune response involves macrophage effector and accessory cell functions as well as T-cell functions (► [Immune Responses](#)).

Innate Immunity

SCID mice infected with *E. histolytica* were used as a model of amoebic liver abscess formation and to study the functional role of neutrophils in vivo. Neutrophil-depleted animals developed significantly larger liver abscesses at early stages of infection, which lacked the prominent inflammatory cell ring observed in control SCID mice. These findings suggest a protective role of neutrophils in the early ► [host response](#) to amoebic infection in the liver (► [Innate Immunity](#)). *E. histolytica* lipopeptidophosphoglycan initiates an innate immune response by interacting with TLR2 and TLR4 and that, through NF- κ B activation, it can regulate an early proinflammatory response followed by an anti-inflammatory response.

B Cells and Antibodies

A majority of *E. histolytica* isolates were found to be lysed by the alternative complement pathway in vitro in the absence of specific antibodies. A protective role of specific antibodies is suggested by experiments using passive immunization protocols of SCID mice. It could be shown that serum or purified antibodies from patients with amoebic liver abscesses were able to significantly reduce the mean abscess size in the experimental animals when applied 24 h before

intrahepatic infection with *E. histolytica*. In addition, specific antibodies against the serine-rich *E. histolytica* protein (SREHP) prevented amoebic liver abscesses in SCID mice. Furthermore, ► **vaccination** with the immunodominant galactose/*N*-acetylgalactosamine-inhibitable lectin of *E. histolytica* induced protective immunity to amoebic liver abscesses at least in some animals, while in others of the same species exacerbation of disease was observed after vaccination. Lotter et al. recently showed that protective immunity is due to the development of an antibody response to a region of 25 amino acid residues of the lectin, while exacerbation of the disease is caused by antibodies against the NH₂-terminal region of the lectin. These findings might be of clinical relevance, since individuals who are colonized with *E. histolytica* but resistant to invasive disease have a high prevalence of antibodies to the protective epitope.

T Cells

There is good evidence suggesting that cell-mediated immunity is centrally involved in the defense against *E. histolytica*. Human and mouse macrophages activated with IFN- γ are able to kill trophozoites in a contact-dependent manner. This killing involves both oxidative and nonoxidative mechanisms. With mouse macrophages, it has been demonstrated that one of the principal effector molecules is ► **nitric oxide (NO)**. The responsible induction of iNOS is enhanced by ► **TNF** produced in an autocrine fashion by stimulated macrophages. The requirement for macrophage activation suggests that a Th1-type immune response might be necessary for an efficient immune response against amoebae. In line with this, T cells from patients with treated amoebic liver abscesses secreted macrophage activating cytokines leading to amoebic killing. IL-2 and IFN- γ production of T cells can be induced by galaxins/*N*-acetylgalactosamine-inhibitable lectin, an immunodominant molecule of *E. histolytica*. The analysis of cytokine production patterns in gerbils infected with *E. histolytica* showed that resistance to reinfection correlated with a Th1-like response.

Amoebiasis, Fig. 2 Human liver with *Entamoeba* abscesses (amoebomas)

Evasion Mechanisms

Patients infected with *E. histolytica* generate specific IgGs that often do not prevent invasive or recurrent infection. One mechanism by which the parasite might avoid binding of the specific antibodies is the production of extracellular cysteine proteases. It has been shown that these proteases cleave IgGs near their hinge region resulting in fragments binding less efficiently to *E. histolytica* trophozoites (► **Evasion Mechanisms**).

The invasion and disease associated with *E. histolytica* has long been connected with suppression of host cellular immunity. Several studies have begun to clarify, at the cellular level, the dampening effects which *E. histolytica* exerts on immune cell and effector cell functions. Although, as discussed above, macrophages are potent cells for amoebicidal activity, the cytotoxic activity of abscess-derived macrophages is reduced during acute hepatic amoebiasis, while macrophages distal from the site of infection are in a heightened state of activity. Obviously, macrophage suppression is a local event, most likely mediated by direct exposure to the parasite or its products. It has been shown that soluble amoebic proteins (SAP) decreased the IFN- γ -induced upregulation of MHC class II molecules on murine macrophages. This inhibitory effect, which is mediated at the transcriptional level, involves the production of prostaglandin E₂ (PGE₂). The fact that inhibition of PGE₂ synthesis by indomethacin reversed SAP-mediated suppression of MHC

Amoebiasis,**Fig. 3** Bloody stool due to *E. histolytica* infection

class II expression by 60 %, establishes that PGE2 induction is the main but not the only mechanism involved. Thus, PGE2 and related products, which may also be produced by *E. histolytica* trophozoites themselves, could indirectly inhibit T-cell receptor recognition of parasite antigens. In addition, pretreatment of macrophages with SAP results in suppression of TNF and ► [nitric oxide](#) synthesis. While addition of indomethacin restored TNF production, it had no effect on iNOS mRNA levels or NO production. Thus, *E. histolytica* appears to have the ability to inhibit different macrophage functions by separate pathways.

To date, T-cell deficiencies in amoebiasis are less well characterized. However, the reduced delayed-type hypersensitivity reaction during acute amoebiasis seen in patients as well as the reduced mitogenic response of purified T cells in vitro argue for a relative paucity of T cells mediating defensive responses against amoebae. A major phosphorylated, lipid-containing glycoconjugate surface molecule of *E. histolytica* may function similarly to ► [lipophosphoglycan](#) (LPG) of ► [Leishmania](#) by inhibiting PKC signal transduction. Other amoebic molecules with potential suppressive roles include a 220 kDa lectin, which induces the production of IL-4 and IL-10.

Main clinical symptoms: ► [Abdominal pain](#), bloody-slimy ► [diarrhea](#) (Fig. 3), liver dysfunction in case of liver abscess (Fig. 2).

Incubation period: 2–21 days.

Prepatent period: 2–7 days.

Patent period: Years.

Diagnosis: Microscopical determination of cysts in fecal samples, ► [Serology](#).

Prophylaxis: Avoidance of uncooked food/water in endemic regions.

Therapy: Treatment see ► [Antidiarrheal and Antitrichomoniasis Drugs](#).

Amoebic Colitis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The process develops as follows:

1. Magna forms of ► [Entamoeba histolytica](#) adhere to colonic mucus via Gal/GalNAc lectin (Galactose/*N*-acetyl-D-galactosamine).
2. Cysteine that is excreted by the amoebae degrades the colonic mucus.
3. The amoebae excrete the protein amoebapore initiating contact dependent apoptotic and necrotic killing of host cells.

4. Amoebic cysteine proteinases activate pre-interleucin 1- β inside the intestinal cells resulting in the occurrence of inflammatory cytokines, which contribute to tissue damage and thus production of hollows.
5. Amoebic invasion in the hollows and lateral spreading produces flask-shaped ulcers with rather low inflammation.

Amoebic Infections

Several species of ► [amoebae](#) (e.g., ► [Entamoeba histolytica](#) causing ► [Amoebiasis](#)) give rise to infections of the intestinal lumen (Protozoan Infections, Man/Table 1). Most are commensal, feeding on bacteria, and producing neither lesions nor functional abnormalities. However, *Dientamoeba fragilis* does give rise to diarrhea often accompanied by ► [eosinophilia](#) in both the stool and blood but without apparent tissue invasion. Its transmission in the absence of a cyst has been linked circumstantially to the nematode ► [Enterobius vermicularis](#).

Therapy

Amoebotaenia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of bird tapeworms, e.g., *A. cuneata* (syn. *A. sphenoides*), is 2–4 mm long and lives in the intestine of chicken and other birds as final hosts and in earthworms as intermediate hosts. It belongs to the family Dilepididae. Humans may become infected occasionally.

Amoebotaenia cuneata

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Tapeworm (2–4 mm long) in chicken and other
 birds with earthworms as intermediate hosts; it
 belongs to the family Dilepididae.

stage, which is formed at the beginning of an
 infection.

Amphilina foliacea

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Amoebozoa

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name

From Greek: *amoibos* = changing, *animan* =
 soon. New phylum of protozoans.

Amoebulum

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Uninucleated stage of ► *Entamoeba histolytica*
 which has been separated from the 8-nucleated

Name

Greek: *amphi* = circularly around. Latin:
linea = line; *foliaceus* = leaf like.

Amphilinidea are regarded as one of the most
 primitive groups of tapeworms (being closely
 related to Monogenea) comprising a few, but,
 worldwide occurring species that parasitize as
 adult worms in fish families such as
 Acipenseridae, Osteoglossidae, Haemulidae, and
 Siluridae. The adult worms are monozoic
 (i.e. they do not have several proglottids but look
 similar to trematodes, Fig. 1) and hermaphroditic
 and possess only a single set of reproductive
 organs. *Amphilina foliacea*, which parasitizes in
 the European species of sturgeons (*Acipenser
 ruthenus*, *A. gueldenstaedti*, *A. stellatus*),
 reaches a length of 2–6 cm, lives in the body
 cavities but also in internal organs of its final
 host (fish) and uses crustaceans (gammarids) as
 intermediate hosts. Related species such as
A. elongata are found in other fish species.
 Together with the genus ► *Gyrocotyle* the
Amphilina species comprise the taxon Cestodaria
 (lower tapeworms).

***Amphilina foliacea*, Fig. 1** *Amphilina foliacea*. 1 Diagrammatic representation of different groups of adult monozoic ► **tapeworms**. *Amphilina foliacea* (about 2–6 cm long) from the body cavity of sturgeons (*Acipenser* sp.); eggs are swallowed by small crustaceans (gammarids), where the ► **proceroid** is formed. When the intermediate host is ingested by the final hosts, the plerocercoid larva develops, reaching maturity in a few days (► **neoteny**) AH Adhesion zone, CR ► **cirrus**, D duct of vitelline glands, DB ► **dense** bodies in the vitelline system, GA genital atrium (joint pore of UT and VE), OV ovary, PB ► **proboscis**, SU sucker, TE testes, UO opening of the uterus, UT uterus, VD vas deferens, VG vagina, VI vitelline glands, VO opening of vagina, and Z interruption (animals are longer)

Name

Greek: *amphi* = at both sides, *stoma* = mouth (two suckers).

See ► **Gastrodiscoides species**.

Amphistostomida

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Order of trematodes, with suckers at both poles,
 e.g., *Paramphistomum cervi* of ruminants.

Amphotericin

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Leishmanicidal drugs, agents against
 Leishmaniasis.

Amplifying Host

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

This term describes animals or humans within
 which parasites reach high/enormous levels so
 that they can be taken up in considerable numbers
 and be transmitted by a vector that feeds on
 these hosts.

Amprolium

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Thiamin analog drug, blocking the thiamin trans-
 port in chicken-coccidia (*Eimeria*), coccidiocidal
 drugs.

Amyloodinium

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name

Greek: *amylon* = starch powder; *oon* = egg;
dinos = armed, dreadful animal.

Life Cycle

This unicellular ovoid parasite of salt water fish
 reaches a size of $150\ \mu\text{m} \times 70\ \mu\text{m}$ at the maxi-
 mum. There are two stages (Figs. 1 and 2):

1. Attached stage: this cyst-like stage is covered
 by a chitinous cover, which is passed by
 rhizopod-like protrusion which enter the skin
 of the fish, so that the parasite is firmly
 attached. Via these 0.15 mm long protrusions
 this parasite of many coral fish obtains its food
 from the fish skin. After feeding an accumula-
 tion of several (name giving) starch, granules
 occurs around its nucleus. Then the parasite
 detaches from the fish and sinks to the floor.

Amyloodinium,

Fig. 1 LM of a sessile
A. ocellatum - stage from a
coral fish

A

Amyloodinium, Fig. 2 Diagrammatic representation of a
swarmer

cover become closed and inside the plasma starts binary fissions, so that finally 256 so-called dinospores are formed, which possess two flagella in grooves of its cover and a red “eyespot”. After rupture of this cyst-like structure the dinospores are set free and now called “swarmer”. In order to survive these stages, they have to find a host within the next 24 h. When being attached at a suitable host, the flagella were reduced and the cytoplasm produces rhizopodes, which enter the skin of the fish.

Symptoms of Disease

The disease due to attached swarmers is called “disease of coral fish”, “velvet skin” or “rust skin”. In case of heavy infections, oxygen uptake via skin is reduced, so that infected fish may die.

Treatment

Flagellol[®] of Fa. Sera, produced by Alpha-Biocare GmbH (Düsseldorf), which is added to water in aquaria.

2. Upon arrival on the ground of the fish biotope, the parasite starts the second = reproductive phase of its life cycle. The ventral openings of the chitinous

Anabiosis

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name

Greek: *anabiosis* = reviveling.

This term describes the ability of many invertebrates to survive bad environmental conditions (drying, freezing). After amelioration of the surviving conditions, these species regain vitality. This phenomenon occurs, e.g., when third stage larvae of strongylids are exposed to bad conditions on meadows in times when potential host had left.

Anal Pruritus

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Skin reaction in humans and horses due to infections with pinworms (► *Enterobius vermicularis*, *Oxyuris equi*) (Alimentary System Diseases, Horses).

Anal Swabs

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Method to detect eggs of, e.g., *Taenia species* and those of ► *Enterobius vermiculatus*, *Oxyuris equi*, or *Passarulus ambiguous*.

Analidae

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Family of skin and feather mites of birds including genera *Leptosphyra* and *Megninia*.

Anamnesis

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name

Greek: *an* = without, no; *mneme* = remembering.

This term describes the individual evaluation of the symptoms of a disease/infection.

Anaphylactic Shock

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Hypersensitivity shock reaction due to repeated setting free of masses of parasitic antigens inside a host (► *Echinococcosis*) fly larvae (► *Myiasis*, *Animals*, ► *Myiasis*, *Man*).

Anapylaxis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the most severe and eventually life-threatening multisystem event of an allergic reaction, which may hit the skin, the respiratory, gastrointestinal, nervous, and cardiovascular system of a person that had come into contact to, e.g., antigenic product of a parasite, bacterium, or food components.

Anaplasma marginale

Bacterium transmitted by *Boophilus*-, *Rhipicephalus*-, and *Dermacentor*-ticks introducing the anaplasmosis of cattle.

Anaplasma phagocytophilum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This organism is a small, 0.4–1.9 μm sized, coccid, pleomorphic, nonmotile, gram-negative bacterium, which lives obligatorily intracellular in the neutrophilic granulocytes and (more rare) in thrombocytes of humans and of other mammals in the USA and in Eurasia (ranging from Portugal to Russia). In the USA ► *Amblyomma americanum* ticks are the main vectors, while in Europe and other regions the ticks *Ixodes ricinus* and *Ixodes persulcatus* are the proven vectors. In seroepidemiologic tests up to 21 % of endangered humans (e.g., forest workers, etc.) had been found seropositive. The disease in humans is called

human granular anaplasmosis (formerly human granular ehrlichiosis, since this bacterium had previously been named *Ehrlichia phagocytophilia* honoring the German microbiologist Paul ► Ehrlich). Although about 80 % of the infections lead only to relatively mild symptoms, 20 % of the infected persons may show severe symptoms, which start after an incubation period ranging from a few days to 4 weeks. Then the disease may start with acute symptoms such as high fever, shivering, headache, muscle pain, and even (in rare cases) meningitis or meningoencephalitis. The blood investigations show leucopenia, thrombocytopenia, and/or anemia. The lethality rates may reach >1 %. For therapy, it is recommended to use doxycycline (2 × 100 mg/day for 10–14 days). Besides humans, sheep, goats, cattle, horses, deer and other wild cervids, dogs, cats, and rodents had been found to carry *A. phagocytophilum*.

Anaplasma platys

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This agent of disease, which is transmitted by the so-called Brown dog tick ► *Rhipicephalus sanguineus*, introduces in dogs (no other hosts are known until now) the so-called cyclic thrombocytopenia, while ► *A. phagocytophilum*

(transmitted by *Ixodes ricinus* and *I. trianguliceps*) induces the granulocytic ehrlichiosis (anaplasmosis). *A. phagocytophilum* is also found in reservoir hosts such as small rodents and in lynx.

Therapy

Good results have been obtained by application of a daily dose of doxycycline of 2×5 mg/kg bodyweight for 2–3 weeks.

Anaplasma Species of Animals

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

There are several tick-transmitted bacteria of the genus *Anaplasma*, which infect mainly or exclusively animals in contrast to ► *Anaplasma phagocytophilum*, which also occurs in humans:

- *Anaplasma centrale* is transmitted to cattle by *Rhipicephalus simus* ticks in South Africa inducing the **benign bovine anaplasmosis**.
- *Anaplasma marginale* is transmitted by ► *Rhipicephalus (Boophilus)* species and by *Dermacentor andersoni* to a broad spectrum of ruminants worldwide in the tropical and subtropical countries inducing the **Malignant bovine anaplasmosis**.
- *Anaplasma mesaeterium* is an apathogenic species that is transmitted by

► *Haemaphysalis punctata* and *Ixodes ricinus* ticks and is found in European sheep.

- *Anaplasma ovis* is transmitted by *Rhipicephalus* and *Dermacentor* species to sheep and goats in the Mediterranean regions, the Near East, and in Africa inducing the anaplasmosis of the small ruminants.
- *Anaplasma platys* (syn. *Ehrlichia platys*) is transmitted by ticks of the species *Rhipicephalus sanguineus* worldwide to dogs inducing symptoms of thrombocytopenia.
- *Anaplasma pullorum* (syn. *Aegyptianella pullorum*). These are transmitted by *Argas* species (*A. persicus*, *A. reflexus*, *A. walkerae*) in Asia, Europe, and Africa to chickens and other birds inducing the disease formerly called aegyptianellosis.

Anatrichosomatidae

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Family of the Trichuridae (subfamily Trichosomodinae), which contains tiny parasites (e.g., *Anatrichosoma cutaneum*, *A. cyanomolgi*), which are found in and on the mucous layer of the nose of monkeys (and sporadically of opossums, cats, and dogs). Extremely rare cases had also been reported from humans. The eggs have a size of $50\text{--}70\text{ }\mu\text{m} \times 35\text{--}42\text{ }\mu\text{m}$ and are characterized like those of ► *Trichuris* species by polar plugs. When excreted within the feces, the eggs already contain the larva 1, which is apparently immediately infectious. Males have no spicula and are somewhat larger than the females.

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Tapeworm of rabbits.

Anemia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *an* = without; *haima* = blood.

This term describes the lack of red blood cells, e.g., due to disruption of ► *Plasmodium* infected red blood cells.

Anergic Diffuse Cutaneous Leishmaniasis (ADCL)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Syndrome of the New World, Leishmaniasis.

Aneuploidy

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

From Greek *an* = no; *en* = true;
pleion = numerous.

This term describes a status of the genome of an individual, where the total number of chromosomes differs from an exact multiple of the haploid chromosomes due to the gain or loss of at least one (but often more) chromosome copies. If fragments of chromosomes are deleted or duplicated, partial aneuploidy is initiated. Aneuploidy (e.g., in case of trisomy of the chromosome 21 in humans) may lead to severe deformations of the individual. However, some parasites (e.g., ► *Leishmania* species) do not show malformations if aneuploidy has occurred. This is the case in *Leishmania braziliensis* and *L. mexicana*, which possess 35 respectively 34 chromosomes due to a unique chromosome fusion process, while the Old World *Leishmania* species such as *L. donovani*, *L. infantum*, *L. major*, and *L. tarentolae* have 36 chromosomes, which are generally considered to represent a

diploid status (a fact which, however, is not sure due to described amplification and/or deletion events). Recent findings underline that *Leishmania* species do not show adverse effects in case of aneuploidy, which is interpreted as a non-Mendelian means to create genetic variation, when recombination is absent or minimal. On the other hand reversion from aneuploidy to the normal state may occur, too. For example, in *Leishmania infantum* additional chromosomes are formed under drug pressure, but disappear as soon as this pressure has stopped.

Aneurysma

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Greek: *aneurysma* = pathologic enlargement of the space between wall and surface layer of an artery.

Angioedema

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes a skin reaction with changing, raised, itchy hives. In case that deeper skin layers

become involved, the tissue produces (often) a considerable swelling (= angioedema) or may even lead to ► [anaphylaxis](#).

Angiostrongylosis

Abdominal Angiostrongylosis is an accidental parasitosis of man by *Angiostrongylus costaricensis* – a species usually found in rats, acquired by eating third stage larvae from slugs or their mucus left on unwashed vegetables. Most of the cases have been found in the Americas, and only a few in Africa. The larvae enter the intestinal wall and migrate to the arteries of the ileocolic region where they become adult (► [Pathology](#), Fig. 23B). The eggs are deposited in the vessel; and are propelled into the intestinal mucosa where they give rise to an intense granulomatous inflammation with eosinophils and fibrosis. Most of the eggs degenerate; although larvae are occasionally

seen in the tissues, they have not been found in the stool where they are shed by the natural host (► [Pathology](#), Fig. 29A–D). Many of the arterioles containing adults become thrombosed after the worms die. The lesions may simulate appendicitis or give rise to large inflammatory ileocolic masses which can cause intestinal obstruction and must be resected surgically. **Cerebral angiostrongylosis** is due to infection with ► *Angiostrongylus cantonensis* (see Fig. 1), showing the following-signs:

Main clinical symptoms: ► [Eosinophilic meningencephalitis](#), paralysis.

Incubation period: 2–3 weeks.

Prepatent period: Larvae are found within 2 days in the brain.

Patent period: Months until the larvae die.

Diagnosis: Serodiagnostic methods.

Prophylaxis: Avoid eating raw food (meat, snails, crabs).

Therapy: Treatment see ► [Nematocidal Drugs, Man](#).

Angiostrongylosis, Fig. 1

Angiostrongylus cantonensis

Synonyms

Parastrongylus cantonensis

Classification

Species of ► **Nematodes**.

General Information

A. cantonensis is an accidental human parasite, normally found in rats (Fig. 1). The worm is acquired by eating undercooked snails or freshwater ► **crustacea**, the intermediate hosts, or fresh vegetables contaminated with larvae in the slime of snails, slugs, or land planaria. The larvae migrate to the meninges and may be found in the spinal fluid. They wander through the brain and occasionally the eye, where they give rise to an acute

Angiostrongylus cantonensis, Fig. 1 Life cycle of *Parastrongylus* (= *Angiostrongylus*) *cantonensis*. (a) Final hosts are rats, where the adult worms (male 19 mm, female 25 mm long) live mainly in the pulmonary arteries. There, the eggs are laid and carried to the pulmonary capillaries, where the first-stage larvae develop within 6 days; these break into the air spaces, migrate up the trachea, are swallowed, and finally passed with the feces. (b) A number of molluscs serve as intermediate hosts, within which the infectious third larval stage (L₃) is formed after two molts. If a rat swallows such intermediate hosts containing infectious L₃ (after about 4 weeks), the larvae

migrate to the rat's brain, which they leave 4 weeks after ingestion, having undergone another molt. About 6 weeks after infection (prepatent period) maturation finally occurs in the pulmonary arteries. (c) A number of animals are involved in the life cycle as paratenic hosts bearing accumulations of infectious larvae. (d) Humans become infected when eating intermediate (b) or ► **paratenic host** tissues (c) containing third-stage larvae. In man these larvae migrate to the capillaries of the meninges, there inducing an ► **eosinophilic meningoencephalitis**. The larvae never become mature worms in man, but eventually die within eosinophilic *granulomas*

inflammatory reaction rich in eosinophils. The meninges may show the main lesions, or the cerebral cortex may be involved with worm tracks, hemorrhages, and large eosinophilic abscesses containing Charcot-Leyden crystals around dead worms. When the worms are near adulthood, they migrate to the branches of the pulmonary artery. In rats, the natural host, eggs and larvae are produced with little inflammation, but in humans the cycle ends as the worms die in the pulmonary arteries.

Life Cycle

Fig. 1.

Angiostrongylus costaricensis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *angeion* = vessel; *strongylos* = round. Latin: *costaricensis* = from Costa Rica, where Morera and Cespedes described this worm first. English: American mesenterial worm. German: Amerikanischer Eingeweidewurm.

Geographic Distribution/Epidemiology

Southern USA, Central America, Venezuela, Colombia, Brazil; due to low sanitary standards many hundred thousands are infected especially in slums of these regions. Recently this worm was also described from human cases in Africa.

Morphology/Life Cycle

The adult worms live in the intestinal mesenterial arteries of rats. Although the cotton rat (*Sigmodon hispidus*) is the most important natural final host, more than ten other rodents, coati-mundi,

marmosets, and even dogs can carry adults. The males measure 17–22 mm × 0.3 mm, while the females are considerably larger (28–42 mm × 0.35 mm). The about 90 µm long and thin-walled eggs are excreted, nonembryonated, and become transported by the blood stream to the blood vessels of the intestinal mucosa, where the larva 1 is developed inside. In case of rats, the larva hatches there (this is not done in the case of humans), migrates into the intestinal lumen, and becomes excreted with the feces. In case slugs (naked snails) feed these larvae 1, the latter grow up within 18 days via larvae 2 and 3, which become excreted with the snail's slime. If rats feed these snails or larvae containing slime, they become infected. After oral uptake, the larvae 3 enter the intestinal wall and migrate to the mesenterial arteries, where they reach maturity after development (larva 4, preadult) within 18–24 days. In humans the worms become adult, their eggs develop the larva 1 inside, but the larvae 1 are unable to leave the eggshell.

Symptoms of Disease

In humans there occur inflammations, thrombosis, and necrosis in parasitized blood vessels. This all together may lead to a life-threatening so-called acute abdomen often in connection with an “ileus verminosus” due to enormous swellings.

Diagnosis

Since in human infections larvae do not hatch from eggs, diagnosis is difficult – there occur no larvae in the feces. Thus there remain only biopsies and trials of serodiagnostics.

Infection

Children: oral uptake of larvae 3 by playing with infected snails.

Prophylaxis

Avoid contact with such snails; keep rats away from surroundings of houses.

Incubation Period

About 3 weeks.

Prepatency

In case of rats about 24 days.

Patency

1–2 years in all final hosts.

Therapy

Drug of choice is tiabendazole (75 mg/kg bodyweight for 3 days). However, surgery may become necessary.

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *angeion* = bottle; *strongylos* = round, cylindric.

► *A. cantonensis*, ► *A. costaricensis*, with *A. mackerrase* in Australia, *A. malaysiense* in Asia, or *A. vasorum* (foxes, dogs – worldwide).

Angiostrongylus vasorum

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *angeion* = vessel, *strongylos* = cylindric; Latin: *vas* = vessel.

Classification

Nematode.

Geographic Distribution

Europe (up to 40 % in foxes, in dogs, and in other canids), Asia, Africa, South America.

Life Cycle

Adult worms (females: 18–24 mm, males: 14–18 mm) appear reddish and live in the arteria pulmonaris and in the right heart chamber of dogs, foxes, and other canids. Eggs are transported to lung, where the larvae hatch and wander via trachea into the throat. Via esophagus they reach the intestinal system and are excreted within feces of their carnivorous final hosts. Further development occurs when snails (e.g., *Arion* species) or frogs take up these larvae 1. Inside these intermediate hosts, development until larva 3 occurs. In case final hosts feed such snails or other intermediate hosts, they become infected, since the larva 3 enters the intestinal wall and reaches via lymph system the heart.

Prepatent Period

6–7 weeks.

Patent Period

Up to 5 years.

Clinical Symptoms

Thrombosis of lung arteries, hemorrhages, dilatation of right heart chamber, dyspnoea, vomiting, ascites, etc.

Diagnosis

PCR diagnosis or demonstration of larvae 1 in feces by help of the ► [Baermann's larval technique](#).

Therapy

Treatment with 20–50 mg/kg bodyweight fenbendazole, milbemycin oxime, or moxidectin plus prophylaxis treatment of thrombosis.

Synonyms

Anguillicola crassus (Moravec et Taraschewski, 1988)

History and Risks

Species of the genus *Anguillicoloides* (syn. *Anguillicola*) are blood-sucking nematodes, parasitizing the swim bladder of eels of the genus *Anguilla* (Fig. 1). *Anguillicoloides crassus* is the most famous of a total of four different species. The parasite originates from the East-Asian and Australian region and was introduced to Europe in the early 1980s, probably by imported, infected Japanese eels *Anguilla japonica*. Afterwards, the nematodes spread across Europe with rapid pace often reaching infection rates of 80–100 % in almost all populations of the European eel *Anguilla Anguilla* (Fig. 1a). Later, the parasite has also been spread to America (1995) and Africa (2006). Recently, *A. crassus* has been listed as one of the 100 “worst” exotic species in Europe, not only because of the human-driven expansion but also due to its critically harmful potential in its new environment. Prevalences and intensities of infections by *A. crassus* are much higher in European eels than in Japanese eels and show an increased pathogenicity. The reason for this

Anguillicola crassus, Fig. 1 *Anguillicoloides crassus*; (a) European eel *Anguilla anguilla*, the final host of *A. crassus*; (b) eel swim bladder of *A. anguilla* showing a typical number of adult blood-sucking *A. crassus*, which can cause heavy infections and might hamper the 5,000 km

long catadromous migration to the Sargasso Sea; (c) nematodes in swim bladder (opened up and well supplied with blood); (d) third-stage larvae of *A. crassus*, isolated from a paratenic fish host

phenomenon is the missing immune response of European eels, while Japanese eels could acquire an immune defense during the coevolutionary process of parasite and host. This explains the Japanese eel's capability to fight and decompose histotrophic larvae (Fig. 1d) of the nematode parasite after vaccination or under high infection pressure.

The European eel has a high economic value since it is considered a culinary delicacy in many European and Asian countries, but since the end of the 1970s, the eel catch size in Europe has decreased by more than 75 %. There are several causes for the decline, e.g., due to strong

anthropogenic pressures induced by fishing, pollutant levels, increasing habitat loss through engineering work on watercourses, as well as so-called turbine losses at hydroelectric power stations, but also natural causes, such as increased predation pressure by fish-eating birds (particularly cormorants) and diseases caused by viruses and especially debilitation caused by the invasive parasite *A. crassus*. High infection rates of *A. crassus* are causing an inflamed and plugged swim bladder and lead to significant impairment of the swimming ability of the eels, especially during the 5,000 km long spawning migration where they need to undertake diel vertical migrations

Anguillicola crassus, Fig. 2 Heteroxenous life cycle of *Anguillicoloides crassus*

(depths of 200–1,000 m). Additionally, a reduced gonad development was detected, which negatively affects the reproduction of European eel. Although there is a strong influence of anthropogenic factors in the distribution of the nematode, the successful spread of *A. crassus* can particularly be attributed to its generalist life cycle, including the incorporation of a broad variety of intermediate host species and a very high reproduction rate.

Life Cycle of *Anguillicoloides crassus*

The life cycle of *A. crassus* (Fig. 2) has been well studied, both in Europe and in Asia. The adult, ovoviparous nematodes are localized exclusively in the swim bladder of its final host *Anguilla* spp. (so far, six species of the genus *Anguilla* are documented to act as final hosts), where it feeds on blood and also reproduces. Each female lays several hundreds of thousands

embryonated eggs, containing the second larval stage (L_2) (the first one (L_1) already developed in the uterus). The L_2 -larvae leave the eel via the *ductus pneumaticus* of the swim bladder and the intestinal tract and thereby pass into the free water column. While most of the L_2 -larvae hatch during the gut passage, some already hatch in the swim bladder where they occasionally penetrate the wall tissue and cause serve inflammation, which often lead to destructive lesions. In the water, the free-living L_2 -larvae attract the first obligate intermediate host by wriggling movements. Until now, 17 different copepod and one ostracod species could be identified as first intermediate host. After penetrating the intestinal tract of the first intermediate host into its hemocoel, the nematode develops its third-stage larva (L_3) within a few days. This larval stage is already infective for the eel, including elvers (once they have left the sea) being susceptible at sizes of only 6–7 cm.

Additionally, different species of fishes (at least 37 fish species known, e.g., Eurasian ruffe *Gymnocephalus cernua*), mollusks (e.g., the snail *Galba corvus*), insects (e.g., the alderfly *Sialis lutaria*), and amphibians (e.g., the newt larvae of *Triturus vulgaris* or tadpoles of the firebellied toad *Bombina bombina*) can be incorporated in the life cycle of *A. crassus* as so-called paratenic hosts. These hosts can accumulate multiple parasites of *A. crassus* (L_3 -larvae mostly stop developing but sometimes develop into fourth-stage larvae) mainly in the body cavity and thus bridge the trophic levels between the larger piscivorous eels and the small copepods. Smaller eels get infected predominantly by feeding on parasitized first intermediate (obligate) hosts, e.g., crustaceans, whereas larger eels mostly prey on infective paratenic (facultative) hosts, e.g., fish or amphibians. Furthermore, a transmission from eel to eel (through cannibalism) is possible.

Once in its final host, the parasite larvae first perforate the eel's gastrointestinal tract and afterwards penetrate into the swim bladder wall by using a trypsin-like proteinase followed by a last molt into its L_4 -stage. Both, the L_4 and the adult stage feed on eel blood (Fig. 1c). After an average of 8–10 months, *A. crassus* reaches sexual maturity and the life cycle restarts. While it takes *A. crassus*

one year to complete its life cycle in the native range, it only takes an average of 8–10 months in the introduced range in Europe. Under optimal conditions of 20–21 °C water temperature it may even happen within only two months, which is likely to promote a faster spreading of the parasite.

Anguillicola Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The genus *Anguillicola* seems to be the only one within the family Anguillicolidae (Laetsch et al. 2012), although Moravec (2006) described a second genus (*Anguillicolides*). The genus *Anguillicola* contains five species (*A. crassus*, *A. papernai*, *A. globiceps*, *A. australiensis*, and *A. novaezelandiae*) which all parasitize the eels found on the different continents. *A. crassus* is best investigated and Dangel et al. (2013) added recently experimental data for *A. novaezelandiae*. Infection of eels occurs by ingesting copepods containing the larvae 3. These larvae then migrate

Anguillicola Species, Fig. 1 Micrograph of the swim bladder of an eel containing a male and female *Anguillicola crassus* worm

from the eel's intestine into its swim bladder, where the adults develop via larvae 4. These adults had been developed within 3–5 months. Within excreted eggs the larvae 2 develops and as soon as copepods or other intermediate hosts feed such eggs, the larvae are set free in their bodies and molt into larva 3. This is the infectious stage, if these copepods or tiny fish (as transport hosts) are ingested by eels, where the adult stages develop inside the swim bladder (Fig. 1). Adults induce internal bleeding, inflammation reactions, dilation of blood vessels, thickening of the swim bladder wall, and granuloma formation. All these reactions plus dead worms found inside the swim bladder minimize the function of the latter and may even kill the fish.

Treatment is difficult and can be tried in fish being kept in ponds by offering levamisole or fenbendazole in the fish food.

Prophylaxis can be achieved by minimizing numbers of ostracods, copepods, etc., in ponds and to feed only deep frozen crustaceans to cultured fish.

Zoonotic disease (anisakidosis) caused by the marine roundworm species of the genus *Anisakis*. Since 1960, the term anisakiasis has been used to designate not only the human disease caused by the third-stage larvae (L3) of *Anisakis* spp. but also the zoonotic disease caused by any member of the anisakid nematode family (Anisakidae). Since 1988 the use of three different terms (anisakiasis, pseudoterranovosis, anisakidosis) is recommended.

Anisakidae (*Anisakis simplex*, *Pseudoterranova decipiens*, *Hysterothylacium*, etc.)

Synonyms

Herring worm; Whale worm

General Information

Highly abundant genus of ascaridoid roundworms (► [Nematodes](#); Figs. 1–3, pp. 87, 88) of the family Anisakidae. The parasites are associated with aquatic organisms and can be found in a variety of marine hosts including whales, crustaceans, fish, and cephalopods.

Life Cycle

The general life cycle (Anisakidae) of these parasites involves broad range invertebrates such as crustaceans and chaetognaths, teleost fish species, and cephalopods, which act as intermediate and/or paratenic hosts. Marine mammals (toothed and baleen whales, sometimes seals) serve as definitive hosts. Toothed and baleen whales of the families Delphinidae, Ziphiidae, Physeteridae, and Kogiidae are considered the main definitive hosts, but members of Balaenopteridae,

Pontoporiidae, Monodontidae, Phocoenidae, and Neobalaenidae have also been documented. Adult *Anisakis* live in the alimentary tract of their definitive hosts where they reproduce. The eggs are dispersed into the surrounding water and are first ingested by smaller crustaceans and then subsequently transferred along the food chain into larger macroinvertebrates (e.g., amphipods, cephalopods). They remain in the hemocoel, where they grow in length and become infective to fish and the definitive hosts. *Anisakis* is capable of infecting larger piscivorous hosts (e.g., cod, *Gadus morhua*) without further molt, which can lead to accumulation of enormous numbers of larvae in the fish.

In the teleost intermediate hosts, *Anisakis* are usually found as curled up shapes encapsulated in the body cavity (e.g., mesenteries) or with sometimes high intensities on the liver or other organs. In salmonid fish (Atlantic salmon, *Onchorhynchus* sp.) the parasites are often encapsulated in the musculature.

Nine species of *Anisakis* are currently described. They have specific definitive hosts of the whale order. Their ecology and genetics differ greatly, although their external appearance is practically identical (cryptic diversity). The existence of morphologically very similar, but ecologically distinct and taxonomically discrete species in the sea probably provides an explanation for the unequally distributed occurrence of anisakiasis (Anisakidosis) in different countries and regions.

Zoogeography

On a genus level, *Anisakis* is distributed worldwide. Recent studies clearly indicate the existence of species-specific distribution areas within the climate zones and oceans that can unequivocally be associated with the distribution and migratory behavior of the respective whale species serving as definitive hosts.

Clinical Relevance

Anisakis larvae are known as the most common exciter of the zoonotic ► [Anisakiasis](#)

(Anisakidosis) when eaten alive in raw or insufficiently cooked fish products (e.g., sushi, sashimi, smoked herring).

³Institute for Ecology, Evolution and Diversity, Goethe-University; Senckenberg Biodiversity and Climate Research Centre; Senckenberg Gesellschaft für Naturforschung, Goethe-University (GU), Frankfurt am Main, Germany

General Information

Zoonotic disease (Anisakiasis, Pseudoterranovosis) caused by the accidental ingestion of live L3 larvae of any member of the ► [nematode](#) family Anisakidae in the flesh of raw, marinated, or undercooked saltwater fish and squid. The

transmission is particularly associated with the consumption of traditional fish dishes such as sushi, sashimi, salted and smoked herring, Spanish *boquerones en vinagre* and other regional specialties whose preparation involves methods of salting, marinating, curing, pickling, and low temperature smoking. Most important with regard to human infections are *Pseudoterranova decipiens* and *Anisakis simplex*, with the latter being the most common exciter. Infections with other anisakids (e.g. *Contracaecum*, *A. pegreffii*) have been documented less frequently.

The worms are often expelled or vomited. Occasionally, they penetrate the gastric or intestinal wall where they give rise to an eosinophilic ► [abscess](#), or in the omentum, or peritoneal lining associated with an adult nematode that may still be alive or dead (► [Pathology](#), Fig. 28D). The specimens are often recovered surgically after an abrupt onset of severe abdominal discomfort. The structures of the worm may be well preserved in acute cases or may have degenerated after an illness of a few days.

Main Clinical Symptoms

Gastrointestinal symptoms, which may be associated with mild to severe immunological reactions. Anisakid larvae are considered to be responsible for four different clinical syndromes:

Gastric

1–12 h after ingestion of live nematodes. Acute symptoms such as severe epigastric pain, nausea, vomiting, low grade fever, and occasionally rash. If untreated, may lead untreated to chronic, ulcer-like symptoms.

Intestinal

5–7 days after ingestion. Mainly restricted to the ileum, sometimes jejunum and colon. Symptoms are intermitting or permanent abdominal pain. Patients may also develop ascites and/or peritoneal signs. Rare complications are small bowel obstruction, ileal stenosis, intussusception, intestinal perforation, and pneumoperitoneum.

Ectopic (Extragastrintestinal/Intraperitoneal)

Larvae penetrate the stomach or intestine which can lead to migration into the peritoneal cavity, pleural cavity, mesentery, liver, pancreas, ovary, and subcutaneous tissue causing pneumoperitoneum.

Allergic

Anisakid antigens are important food-borne allergens causing responses ranging from intermediate urticaria to severe anaphylaxis and sometimes gingivostomatitis 4–48 h after ingestion of parasites. In the case of *Anisakis*, infection provokes specific immune responses by all antibody isotypes (IgE, IgG, IgA, IgM) in more than 10 % of gastrointestinal anisakiasis. Anisakis antigens are included in standard skin prick tests for food-borne allergies.

► [Abdominal pain](#), intermittent ► [diarrhea](#), loss of weight.

Incubation Period

1 h–1 week.

Prepatent Period

Larvae are present from the moment of oral uptake.

Patent Period

Weeks until the worms have been killed within granulomas.

Diagnosis

Gastroscopical methods. Infections can be misdiagnosed as peptic ulcer disease or gastritis and extraintestinal infections can be confused with acute peritonitis, tuberculous peritonitis and pancreatic cancer.

Prophylaxis

Preventive measures such as the use of temperatures of ≥ 60 °C for at least 1 min when cooking and freezing at temperatures lower than -20 °C for at least 24 h of fish to be eaten raw has been recommended to kill the parasites and prevent live infections. The risk of human infection can also be reduced by visual examination of fish and the extraction of visible parasites.

Therapy

Treatment see ► [Nematocidal Drugs](#), [Man](#).

Anisakis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Disease

► [Anisakiasis](#).

Genus of roundworms (Nematodes; Figs. 1–3).

Anisakis, Fig. 1 Life cycle of marine ascarids (e.g., ► *Contracaecum* spp., *Phocanema* sp. = *Terranova*, ► *Pseudoterranova* sp., *Anisakis* sp.). 1 Adult worms live in the intestine of fishes or sea mammals (final hosts). 2 Eggs are unembryonated when fecally excreted. 3–5 Formation of L₁ and L₂ apparently occurs inside the eggs floating in the water. 6 Apparently, a wide range of small marine crustaceans may act as intermediate hosts when ingesting infectious eggs. Inside the intermediate host the L₃ is formed (in some species free L₃ has also been suggested). 7 When these L₃-bearing crustaceans are swallowed by a wide range of fish, the third-stage larvae are spirally encapsulated and thus accumulated inside various organs, including muscles, without further development. Some authors believe that development to L₄ occurs. 8 Infection of final hosts occurs by oral uptake of infected fish. Inside the stomach and intestine, ulcerations (by embedded groups of larvae and preadults) and even perforations of the intestinal wall have been described. 9 Humans who can be accidentally infected by eating raw or insufficiently cooked meat of infected fish (e.g., green herring) may become some sort of ► *paratenic host* and suffer from an acute ► *anisakiasis* as a result of the penetration of larvae into the walls of the stomach and/or intestine; this can lead to death. Over the last 50 years,

the specific name of “codworm” or “sealworm” has changed several times. Once it was called *Ascaris decipiens* (*decipiens* means deceiving); it later became *Porrocaecum decipiens*, then *Terranova decipiens*. Myers created a new genus for this worm, proposing the name *Phocanema decipiens*, but reexamination of the concept and validity of anisakid in general led to the conclusion that *Phocanema* was a synonym of *Pseudoterranova* Mosgovoi, 1951. This criterion has been gradually accepted and *Pseudoterranova decipiens* is found in current literature. *Terranova* sp. larva Type A, as referred to in Japanese literature, is definitely the third-stage larva of this *P. decipiens*, which is commonly called ► *codworm*. Similarly, various names have been applied to the human disease caused by codworm. Margolis suggested restriction of “anisakiasis” to denote infection with anisakid larvae of the genus *Anisakis*, using “nonspecific anisakiasis” when the larva has not been identified to genus or as a collective term for infection with anisakid larva, and “phocanemal (or terranomal) anisakiasis” for infections with larvae of genus *Phocanema*. But the genus *Terranova* is now restricted to the parasites of elasmobranchs, teleosts, and aquatic reptiles, and the genus *Phocanema* has been abandoned. However, “pseudoterranomal anisakiasis” would be an impractical name for clinicians, so the term “codworm anisakiasis” is preferred.

Anisakis, Fig. 2 Schematic representation of diagnostically useful intestinal features of human pathogenic marine anisakids (a–c). A anus, DA intestine, DB intestinal enlargement, DO thorn, NR nerve ring, OE esophagus, VB enlargement of ventriculus, and VE ventriculus

Anisakis, Fig. 3 Ice fish (*Macrourus* sp.) from the Antarctic sea, the liver of which is filled with anisakid larvae

Anisakis Gastroallergic Reactions

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

In case of ingestion of living or dead stages (larvae) of ► *Anisakis simplex* or related species within raw fish, an acute allergic reaction may occur. The symptoms described from affected persons are: urticaria, angioedema, etc.

► *Gregarines*, Fig. 1) while ► *Coccidia* (e.g., ► *Plasmodium*, ► *Eimeria*) have macro- and ► microgametes.

Anisakis Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Besides *A. simplex*, larvae of further species may infect humans accidentally: *A. pegreffii*, *A. physeteris*, *A. paggiae*, and *A. brevispiculata*.

Anisus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of snails, intermediate hosts of
► *Paramphistomum*.

Anncallia

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

New genus name for *Nosema algerae* genotype 1, which occurs in AIDS patients.

Annelida

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Anisogametes

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Gametes of different sexes that vary in size and shape occurring, e.g., in ► *Apicomplexa* (e.g.,

Classification

Phylum of ► *Metazoa*.

General Information

The annelids were named with respect to their outer annulated appearance, which apart from Hirudinea corresponds to an inner, more or less

homonomous segmentation. Most of the annelids are free-living species; blood-sucking ectoparasites are mainly found among the members of the subclass Hirudinea (► [Leeches](#)).

System

The classification of the Annelida is still in discussion; however, the following groups are widely accepted:

Phylum: Annelida

Class: Polychaeta (mainly free-living)

Class: ► [Myzostomida](#) (parasites of Crinoidea)

Class: Clitellata

- Subclass: Oligochaeta (mostly free-living)
- Subclass: Hirudinea (some parasitic species)

Annual Parasite Index

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term is defined by the number of clearly diagnosed malaria cases in a special region during one year per total number of humans multiplied by 1,000.

Annual Transmission Potential (ATP)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

A factor that determines the burden of infection in a human community, e.g., in onchocerciasis. It is determined by the number of infectious larvae 3 transmitted per year by the biting black fly vector (► [Simulium](#) species).

Annulotrema

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of monogeneantrematodes of fish. E.g., *A. uncata*, *A. pikei*, *A. besalis* from tiger fish (*Hydrocynus brevis*).

Further Reading

Rehulkova E et al (2014) *Annulotrema* from *Hydrocynus brevis* in Senegal. Parasitol Res 113:3273–3280

Anocentor

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of hard ► [ticks](#). *Anocentor* (syn. *Dermacentor*) *nitens* (the tropical horse tick) is found in Latin America. It is a one-host tick, e.g., all stages stay on its first host.

Anopheles

► [Diptera](#), ► [Filariidae](#), ► [Mosquitoes](#).

Anopheles stephensi

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The mosquito species *A. stephensi* belongs to the most important vectors of the agents of malaria,

Anopheles stephensi, Fig. 1 Light micrograph of a female sucking sugar solution

Anopheles stephensi, Fig. 3 *A. stephensi*, female in flight: note the long legs

Anopheles: Subgenera

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Anopheles, Cellaia, Kerteszia, Nyssorhynchus

Anophelism

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Phenomenon of the cohabitation of a species complex consisting of different *Anopheles* species with completely different behavior (e.g., salt and fresh water breeders) and different feeding options in a region where malaria is suspected to become transmitted.

Anopheles stephensi, Fig. 2 *A. stephensi*, male in flight: note the bushy antennae

which are transmitted during the blood sucking of the females. (See Figs. 1, 2, and 3).

Anoplocephala magna, A. perfoliata

Tapeworm of horses, ► Eucestoda, ► Alimentary System Diseases, Horses.

Anoplocephala Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *anoplos* = unarmed, *kephale* = head; Latin: *foliatus* = with leaves; *magna* = large, big; *deminuere* = making smaller; Greek: *gigantos* = giant; Latin: *gorilla* = monkey; *latissimus* = largest; *mammilatus* = with nipples; *rhodesiensis* = from Rhodesia = today Zimbabwe.

Geographic Distribution/Epidemiology

Worldwide.

Morphology/Life Cycle

The different species of the *Anoplocephala* have different host preferences:

A. diminuta: rhinoceros, India
A. gigantea: rhinoceros, Africa
A. gorillae: monkeys, Africa

Anoplocephala Species, Fig. 1 Light micrograph of two *Anoplocephala* worms in their constricted form inside feces

A. latissima: rhinoceros, Asia
A. magna: horses and related species, worldwide
A. manubriata: elephants, India, Africa
A. mamillana: horses, worldwide
A. perfoliata: horses and related species, worldwide
A. rhodesiensis: elephants, horses, and related groups, Africa, worldwide

Most of the adults are short and reach only a length of up to 4 cm, while, e.g., *A. perfoliata* measures 25 cm, but shrinks in feces to 5 cm. *A. magna*, *A. latissima*, and *A. gigantea* measure up to 1 m in length. The scolex has four suckers but no rostrum (Figs. 1, 2, and 3). The proglottids are broader than long and the tetraedic eggs measure 60–80 µm in diameter.

Intermediate hosts are oribatid mites, within which the infectious cystercoïd stages develop.

Anoplocephala Species, Fig. 2 Scanning electron micrograph of the anterior poles of *Anoplocephala* worms. LP lobe-like protrusion, SC scolex, SN sucker

Anoplocephala Species, Fig. 3 Scanning electron micrograph of the scolices of *Anoplocephala* worms. LP lobe-like protrusion, SC scolex, SN sucker

Symptoms of Disease

In cases of heavy infections severe disturbances of digestion may occur: cramps, diarrhea, weight

Anoplocephala Species, Fig. 4 Light micrograph of an egg of *Anoplocephala* sp. ON oncosphaera

loss. However, low graded infections remain symptomless.

Diagnosis

Proglottids occur in feces as well as eggs, which can be isolated by S.A.F. or M.I.F. techniques (Fig. 4). Egg size is 60–80 μm , they are polymorphic.

Infection

Oral uptake of intermediate host within food (= oribatid mites).

Prophylaxis

Keep meadow dry.

Incubation Period

4–10 weeks.

Prepatency

4–10 weeks.

Patency

6–12 months.

Therapy

Praziquantel (1 mg/kg bodyweight, oral).

Anoplocephalidae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *anoplon* = unarmed; *kephale* = head.

General Information

This family of tapeworms contains several genera with a variety of species. Several of them are important parasites of farmed animals.

Species	Hosts	Distribution
► <i>Anoplocephala Species</i>	Horses, donkeys, equids	Worldwide
► <i>Avitellina centripunctata</i>	Ruminants	Southern Europe, Asia, Africa

(continued)

Species	Hosts	Distribution
► <i>Bertiella Species</i>	Monkeys, humans	Worldwide
► <i>Cittotaenia pectinata</i>	Rabbits	Worldwide
<i>Killigrewia delafondi</i>	Pigeons, doves	Worldwide
<i>Moniezia</i> species	Ruminants	Worldwide
► <i>Paranoplacephala mamillana</i>	Equids	Worldwide
<i>Stilesia globipunctata</i>	Ruminants	Europe, Asia, Africa
<i>Thysaniezia giardi</i>	Ruminants	Europe, Asia, Africa
► <i>Thysanosoma actinoides</i>	Ruminants	South, North America

The adults which have four suckers, but no rostellum and hooks, live in the intestine of their vertebrate host, while oribatid mites are involved as intermediate hosts, which contain the ► **cysticercoid** larvae. **Symptoms of disease** were described as: diarrheas, retarded growth or loss of body weight, and cramps. **Diagnosis** is done by microscopical demonstration of the proglottids and eggs, which contain an onchocerca larva.

Therapy

Use of praziquantel; ► **cestodocidal drugs**.

Anoplocephaloides bulmeri

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Cestode of the Southern bog lemmings.

Anthelmintic

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Describes a reaction or compound that acts against worms (Greek: *anti* = against, *helminthes* = worms).

Anthelmintic Drugs Advancements

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Ongoing process of development of resistances against anthelmintics (especially in veterinary use) makes it necessary to develop and introduce new compounds. Very recent compounds are:

- Emodepside (a cyclooctadepsipeptide)
- Monepantel (an amino acetonitrile derivative)
- Derquantel (2-deoxy-paraherquamide, class of spiroindols)

Epe and Kaminsky (2013) summarized recent proven activities of these compounds (Table 1).

References

Anthroponoses

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Diseases affecting only humans. The major representatives of parasitic anthroponoses are listed in Table 1 (page 92).

Anthroponoses, Table 1 Important parasitoses which are usually restricted to humans as vertebrate hosts

Parasite species	Infective stage	Mode of infection	Other obligatory hosts	Disease
Protozoa				
<i>Trypanosoma gambiense</i>	Metacyclic trypanosome	Bite of <i>Glossina</i> spp.	<i>Glossina</i> spp.	Sleeping sickness (Gambian)
<i>Trichomonas vaginalis</i>	Trophozoite	Mainly sexual intercourse	None	Human trichomoniasis
<i>Hartmannella</i> spp.	Vegetative forms (cysts?)	Entry through nasal mucosa	None	Amoebic meningoencephalitis
<i>Acanthamoeba</i> spp.				
<i>Naegleria</i> spp.				
<i>Plasmodium falciparum</i>	Sporozoite	Bite of <i>Anopheles</i> spp.	<i>Anopheles</i> spp.	Falciparum malaria
<i>Plasmodium ovale</i>	Sporozoite	Bite of <i>Anopheles</i> spp.	<i>Anopheles</i> spp.	Ovale malaria
<i>Plasmodium vivax</i>	Sporozoite	Bite of <i>Anopheles</i> spp.	<i>Anopheles</i> spp.	Vivax malaria
Trematodes				
<i>Schistosoma haematobium</i>	Cercaria	Transdermal invasion	<i>Bulinus</i> spp.	Urinary schistosomiasis (bilharzia)
<i>Schistosoma intercalatum</i>	Cercaria	Transdermal invasion	<i>Bulinus</i> spp.	Schistosomiasis intercalatum
<i>Schistosoma mansoni</i>	Cercaria	Transdermal invasion	<i>Biomphalaria</i> spp.	Mansonian schistosomiasis
Nematodes				
<i>Ascaris lumbricoides</i>	Eggs containing second-stage larva	Ingestion	None	Human ascariasis
<i>Enterobius vermicularis</i>	Eggs, larvae entering the anus	Ingestion	None	Human pinworm infection
<i>Trichuris trichiura</i>	Embryonated egg	Ingestion	None	Human trichuriasis
<i>Ancylostoma duodenale</i>	Strongyliform larva	Transdermal invasion	None	Human ancylostomiasis
<i>Necator americanus</i>				
<i>Wuchereria bancrofti</i>	Filiariform third-stage larva	Mosquito bite	Mosquitoes (<i>Culex</i> , <i>Aedes</i> , <i>Anopheles</i> , <i>Mansonia</i> spp.)	Lymphatic (bancroftian) filariasis
<i>Onchocerca volvulus</i>	Filiariform third-stage larva	Blackfly bite	<i>Simulium</i> spp.	Onchocerciasis

Therapy

► [Chemotherapy](#), ► [Drugs](#).

prefer human beings to animals or accept humans as well as animals as hosts.

Anthroponotic Disease

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *anthropos* = human.

Infectious disease, the agents of which are transmitted exclusively between humans: e.g., lung tuberculosis, malaria, ascariasis, enterobiasis, etc.

Anthropozoonoses

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Synonyms

Zooanthroponoses (See also Table 1).

Anthropophagic

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

► [Mosquitoes](#) that feed predominantly on humans (e.g., several ► [Anopheles](#) species) are referred to as anthropophagic. However, hungry females also choose other hosts in case of the absence of their favorites.

General Information

Diseases affecting both man and other animals. The major representatives of parasitic ► [zoonoses](#) are listed in Table 1.

Therapy

► [Chemotherapy](#), ► [Drugs](#)

Anthrophilic Parasites

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The name comes from Greek *anthropos* (human) and *philein* (to love) and describes parasites that

Antibiotics

Günter Schaub
Parasitology, Ruhr University, Bochum, Germany

General term to describe drugs acting in various ways on bacteria (e.g., they may have bacteriostatic (tetracyclines) or bacteriocidal (e.g., penicillins) activities. See ► [Lyme Disease](#), ► [Streptothricosis](#), ► [Borreliosis](#), and ► [Rickettsiae](#).

Anthropozoonoses, Table 1 Important zoonothronotic and anthroponozoonotic parasitoses (according to Wernsdorfer)

Parasite species	Principal hosts (besides humans)	Infective stage	Mode of infection	Other obligatory hosts	Disease
Protozoa					
<i>Leishmania donovani</i>	Various domestic animals	Promastigote	Sand fly bite	<i>Phlebotomus</i> spp.	Visceral leishmaniasis (kala-azar)
<i>Leishmania tropica</i>	Dogs	Promastigote	Sand fly bite	<i>Phlebotomus</i> spp.	Oriental sore
<i>Leishmania braziliensis</i>	Dogs	Promastigote	Sand fly bite	<i>Phlebotomus</i> spp.	Mucocutaneous leishmaniasis (espundia)
<i>Trypanosoma rhodesiense</i>	Wild and domestic mammals	Metacyclic trypanosome	<i>Glossina</i> bite	<i>Glossina</i> spp.	Sleeping sickness (Rhodesian)
<i>Trypanosoma cruzi</i>	Wild and domestic mammals	Metacyclic trypanosome	Invasion through bite wound from reduviid feces	Reduviid bugs (<i>Triatoma</i> , <i>Panstrongylus</i> , <i>Rhodnius</i> spp.)	Chagas disease
<i>Giardia duodenalis</i>	Wild and domestic mammals	Cyst	Ingestion	None	Lambliasis (giardiasis)
<i>Balantidium coli</i>	Pigs	Cyst	Ingestion	None	Balantidiasis (dysentery)
<i>Entamoeba histolytica</i>	Various mammals	Cyst	Ingestion	None	Amoebiasis (dysentery and amoebic abscesses)

<i>Babesia bigemina</i>	Cattle	Sporozoite	Tick bite	Ticks (especially <i>Boophilus</i> spp.)	Texas cattle fever, babesiosis
<i>Babesia canis</i>	Dogs	Sporozoite	Tick bite	Ticks (various spp.)	Canine babesiosis
<i>Plasmodium malariae</i>	<i>Pan troglodytes</i>	Sporozoite	Bite of <i>Anopheles</i> spp.	<i>Anopheles</i> spp.	Quartan malaria
Trematodes					
<i>Fasciola hepatica</i>	Sheep, cattle	Metacercaria	Ingestion	Aquatic snails (<i>Lymnaea</i> , <i>Succinea</i> , <i>Fossaria</i> , <i>Praticolella</i> spp.)	Fascioliasis (liver rot of sheep and cattle)
<i>Fasciolopsis buski</i>	Pigs	Metacercaria	Ingestion	Aquatic snails (<i>Planorbis</i> and <i>Segmentina</i> spp.)	Fasciolopsiasis
<i>Dicrocoelium dendriticum</i>	Various domestic mammals	Xiphidiocercaria	Ingestion with ants	Land snails (mainly <i>Cionella</i> spp.) followed by ants (mainly <i>Formica fusca</i>)	Dicrocoeliasis
<i>Opisthorchis felineus</i>	Felines	Cercaria	Ingestion	Aquatic snails (<i>Bithynia</i> spp.) followed by cyprinid fish	Opisthorchiasis

<i>Clonorchis sinensis</i>	Canines, felines	Cercaria	Ingestion	Various aquatic snail species, followed by cyprinid fish	Clonorchiasis
<i>Paragonimus westermani</i>	Cats	Metacercaria	Ingestion	Mollusks (<i>Semisulcospira</i> , <i>Tarebia</i> , <i>Brotia</i> spp.), followed by crustaceans (mainly freshwater crabs)	Paragonimiasis
<i>Paragonimus kellicotti</i>	Canines, felines, and other mammals	Metacercaria	Ingestion	Aquatic snails followed by crayfish	Paragonimiasis
<i>Schistosoma japonicum</i>	Wild and domestic mammals	Cercaria	Transdermal invasion	<i>Oncomelania</i> spp.	Japanese schistosomiasis
Cestodes					
<i>Diphyllobothrium</i> spp.	Canines, felines, and other fish eaters	Proceroid	Ingestion	Copepods (e.g., <i>Diaptomus</i> spp.), followed by fish	Fish tapeworm infection
<i>Taenia solium</i>	Pigs (adult worm), cysticercus, also in other animals	Egg and cysticercus	Ingestion	No obligatory host species alternation	Cysticercosis cellulosae and pig tapeworm infection
<i>Taenia saginata</i>	Cattle (cysticercus), humans (adult worm)	Cysticercus	Ingestion	Humans (adult worm), cattle (cysticercus)	<i>Taeniasis saginata</i> (cattle tapeworm infection)
<i>Echinococcus granulosus</i>	Canines (adult worm), various mammals (hydatid cysts)	Egg and hydatid larva	Ingestion	Canines (adult worm), various mammals (hydatid cysts)	Hydatid disease
<i>E. multilocularis</i>	Fox, dogs, mice	Egg for man, alveolar cyst for fox	Ingestion	Mice, many animals	Alveolar disease
<i>Hymenolepis nana</i>	Rodents	Egg	Ingestion	None	Hymenolepiasis nana
<i>Hymenolepis diminuta</i>	Rodents	Cysticercoid larva	Ingestion with infected roach	Roaches (<i>Tembrio</i> , <i>Pyrallis</i> , <i>Anisolabis</i> spp., etc.)	Hymenolepiasis diminuta
Nematodes					
<i>Angiostrongylus cantonensis</i>	Rats	Third-stage ensheathed larva	Ingestion with infected slug or snail	Slugs and aquatic snails	Human angiostrongyliasis (eosinophilic meningencephalitis)

(continued)

Anthropozoonoses, Table 1 (continued)

Parasite species	Principal hosts (besides humans)	Infective stage	Mode of infection	Other obligatory hosts	Disease
<i>Ascaris lumbricoides</i>	Various vertebrates	Egg with second-stage larva	Ingestion	None	Ascariasis
<i>Toxocara canis</i>	Canines	Embryonated egg or second-stage larva	Ingestion	None	Human visceral larva migrans
<i>Toxocara cati</i>	Felines				
<i>Anisakis</i> spp.	Marine mammals and birds	Third-stage larva	Ingestion of fish meat	Insufficiently known, mostly fish	Human anisakis infection (due to third-stage larvae)
<i>Trichinella spiralis</i>	Various mammals	Infective larva	Ingestion	None	Trichinellosis
<i>Gnathostoma spinigerum</i>	Canines and felines	Third-stage larva	Ingestion	<i>Cyclops</i> spp., followed by fish, frogs, or snakes	Gnathostomiasis
<i>Capillaria hepatica</i>	Various mammals	Embryonated egg, after passage through “transport” host	Ingestion	Only “transport” host	Capillariasis, human visceral larva migrans
<i>Strongyloides stercoralis</i>	Various mammals	Filariform larva	Transdermal penetration	None	Strongyloidiasis of humans and sheep
<i>Dracunculus medinensis</i>	Canines, felines, equines, monkeys	Third-stage larva	Ingestion (with <i>Cyclops</i>)	<i>Cyclops</i> spp.	Guinea worm disease
<i>Brugia malayi</i>	Felines and nonhuman primates	Filariform third-stage larva	Mosquito bite	Mosquitoes (usually <i>Anopheles</i> and <i>Mansonia</i> spp.)	Lymphatic (brugian) filariasis
<i>Loa loa</i>	Baboons	Third-stage larva	Tabanid bite	Tabanids (<i>Chrysops</i> spp.)	Loiasis

Synonyms

Immunoglobulin (Ig)

General Information

The function of antibodies is to remove antigens from the system and to support an effective immune response. Circulating antibodies which are detected in serodiagnostic systems are secreted by antibody-forming cells (plasma cells) after contact between B cells and antigen. They circulate freely throughout the blood and lymph. Antibodies are bifunctional molecules with antigen-binding sites (Fab fragment) and a region which is involved in other aspects of the immune regulation (Fc fragment). In most higher mammals and man, four of the five immunoglobulin classes of molecules are involved in the humoral immune response to parasites: IgG, IgM, IgA, and IgE.

Classes

Each immunoglobulin class differs in the heavy-chain polypeptides which determine its function at particular stages of the maturation of the immune response. IgM class antibodies are predominately antibodies of the early immune response and are distributed to a high degree intravascularly. A specific IgM class antibody response is indicative for an acute infection mainly with protozoan parasites. IgM serodiagnostic tests are used to discriminate between acute/recent and latent infections with *Toxoplasma*, *Trypanosoma cruzi*, and ► *Babesia*. In contrast, during the early phase of West ► *African trypanosomiasis* specific IgM antibodies may be undetectable in spite of a rising total

serum IgM concentration. In helminthic infections, diagnostic IgM class antibodies do not necessarily proceed an IgG response. This may be due either to a “diagnostic window” as seen 4–6 weeks after *Trichinella* infection or, e.g., to the late onset and long-term persistence of gut-associated IgM antibodies after ► *Schistosoma* infection. The human IgG, which can be subdivided into the four subclasses IgG1–IgG4, is the major antibody of the primary and secondary immune response and the major serum immunoglobulin. In chronic ► *helminth* infections elevated IgG- and IgE-specific responses develop. The prominent IgG subclasses recognizing parasite-specific antigens are IgG4 > IgG1 > IgG3, rarely IgG2. A high IgG4 response may indicate a successful parasite infection. The detection of parasite-specific IgG4 is essential for a species-specific diagnosis of ► *Onchocerca volvulus*, ► *Wuchereria bancrofti*, ► *Strongyloides*, ► *Ascaris*, and ► *Echinococcus*. IgG molecules of all subclasses can cross the placenta. Only the detection of specific IgM and/or IgA in the serum of the fetus or newborn is of relevance for the serological diagnosis of congenital infection with *Toxoplasma*, *Trypanosoma cruzi*, or ► *Leishmania*. IgM and IgG1–3 antibody classes are able to activate the complement cascade, but not IgG4, IgA, and IgE. IgA is the predominant immunoglobulin in seromucous secretion, IgA1 being the predominant subclass in the serum. IgA antibodies are of additional value as markers for an acute infection as documented for toxoplasmosis. An elevation of total serum IgE, but not necessarily specific IgE class antibodies, is often related to infections with helminth parasites and may indicate an active disease. In contrast, protozoan parasites do not induce a significant IgE class antibody response. Specific IgE is not a reliable diagnostic marker for acute *Toxoplasma* infection due to many non- or low-responders within the population.

Molecular Weights

IgM approx. 970,000 Da; IgG approx. 146,000 Da; IgA approx. 160,000 Da; IgE approx. 188,000 Da; IgD approx. 184,000 Da.

Binding Sites and Affinity

Antibodies are highly specialized in recognizing small regions of antigens but occasionally recognize similar epitopes on other related or unrelated molecules (cross-reaction). The binding between the antibody and the epitope of the antigen is noncovalent. The strength of bond between an antibody-combining site and an antigen is characterized as antibody affinity, and the strength with which a multivalent antibody binds a multivalent antigen is antibody avidity. The antibody affinity/avidity to many antigens increases during an immune response and determines the biological effectiveness of the antibody. High-affinity antibodies are superior to low-affinity antibodies in respect to many biological reactions (e.g., hemagglutination, complement fixation) and in achieving antigen binding more effective even at low antigen concentration. Today, this immunological mechanism is utilized for the differential diagnosis of a recent and latent *Toxoplasma* infection in man.

Half Lives

The half-life of antibodies differs according to the antibody classes. It is high for IgG (21 days), medium for IgM (10 days), and low for IgA and IgE (6–2 days). The complexed antibody is catabolized before clearance.

Biological Activity

In general, a primary antibody response can be divided into four phases: a first period when no antibodies are detectable, followed by an immune response of primarily IgM antibodies with a progressive change to IgG antibodies and an increasing antibody titer. The plateau phase with stable antibody titers is followed by an antibody decline. During ► *chronic infections*, when the parasite is established at its permanent habitat, antibody

production is mainly stimulated by circulating (excretory-secretory) antigens. The antibody secretion by B cells continues as long as the antigen(s) persists. Persisting antigen may increase the strength of the immune response. The primary antibody response is not only influenced by the nature of the antigen, its dose, and infection route but also by the genetic background of a host. The time of antibody maturation and the final antibody concentration can vary considerably in individuals. Especially low responders or people with a recently contracted infection or patients from low endemic areas may not be detected in all serological test systems. Seroepidemiological studies in *L. infantum*-infected dogs indicate that a high sensitivity of the IFAT is reached only after an ► *incubation period* of 8–9 months when first clinical symptoms occur. A complete antibody clearance is only possible after a complete elimination of the parasite (blood parasites after therapy) or its antigenic epitopes. Also, antigenic epitopes may be hidden by “walling off” in the host tissue (*Echinococcus*, ► *Cysticercus*). However, after elimination of the antigen specific lymphocytes remain in circulation and may respond to a subsequent challenge (immunological memory). A challenge by antigens released after surgical or therapeutical measures (*Echinococcus*, *Cysticercus*) or reinfection induces a ► *secondary antibody* production with a steep increase of mainly IgG class antibodies.

Clinical Relevance

Generally, the presence of circulating antibodies indicates the recognition of a foreign antigen. In parasitic infections antibody detection does not correlate with disease, protective immunity, or the parasite load. The serum antibodies are the most important defense mechanism of the host against extracellular parasitic forms in blood and body fluids like ► *Trypanosoma*, *Toxoplasma*, ► *Plasmodium*, or *Babesia* during acute infection. Symptomatic individuals normally present high

antibody levels, whereas asymptomatic carriers show a low antibody concentration. Antibodies in individuals without clinical symptoms may indicate an abortive infection as described for *E. multilocularis* or an infection with a long latency/incubation period. A correlation between cyst burden and antibody detection is known for porcine and human ► [cysticercosis](#) (► [Taenia solium](#)). ► [Cysticercosis](#) or ► [echinococcosis](#) in asymptomatic or symptomatic patients is not excluded by negative test results. An assessment of the parasite load is not possible by conventional serological test systems. Recent developments indicate that specific antibody assays are useful for the determination of the egg load after *Schistosoma* infection. However, a better quantitation is by direct and indirect immunoassays which measure circulating parasitic antigens in body fluids. The quality of antibodies induced after natural infection or vaccination may differ in many aspects. It has to be considered that postvaccination antibodies may not be detectable in conventional test systems. An evaluation of parasitic treatment is difficult by ► [serology](#). Only a complete parasitological cure is confirmed by negative serological results. Antibody disappearance is described for hepatic fascioliasis in humans 6–12 months after specific therapy and goats 1–5 months after therapy. In patients with Chagas' disease humoral response may persist for years after a negative result in direct parasite examination. This is also true for schistosomiasis, echinococcosis, cysticercosis, and filariasis. However, there are promising results that a follow-up of the antibody response to selected antigen(s) may be efficient in posttherapeutic monitoring.

In parasitic infections the antibody isotype profiles may vary with time and the clinical manifestation. Differences in the IgG isotype pattern of the paired sera from mother and newborn add to the diagnosis of congenital toxoplasmosis. Congenital toxoplasmosis or congenital infection with *Trypanosoma cruzi* is proven by the demonstration of specific IgM and/or IgA antibodies in the newborn serum.

Antibody-Dependent Cellular Cytotoxicity (ADCC)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Antidiarrheal and Antitrichomoniasis Drugs

Wolfgang Raether

Hoechst, Frankfurt, Germany

Drugs Acting on Giardiasis

► [Giardia lamblia](#) (syn.: *G. intestinalis*, *G. duodenalis*) is distributed worldwide and has been identified in humans and domestic livestock, particularly in young animals such as calves, lambs, piglets, and foals and birds. The flagellate (with four pairs of ► [flagella](#)) living in the small intestine may produce acute or chronic enteritis with profuse and heavy diarrhea and growth rate

reduction in mammals and birds. *Giardia* spp. infections in animals may pose a serious zoonotic threat to humans. Humans may acquire infection either through waterborne transmission by *Giardia* cysts occurring in the drinking water contaminated with infectious feces or by direct contact with contaminated feces. Although quinacrine and furazolidone resistance has been induced in *G. duodenalis* ► **trophozoites**, the substituted acridine dye derivative quinacrine can be of value in humans suffering from giardiasis, mainly in patients showing reduced response to 5-nitroimidazoles. However, quinacrine may cause exacerbation of psoriasis, ocular toxicity, and toxic psychoses or distinctly enhance toxicity of 8-aminoquinolines, e.g., primaquine (► **Malariacidal Drugs**).

Benzimidazole carbamates such as mebendazole, fenbendazole, or albendazole may exhibit the most pronounced activity against *Giardia* infections in man, farm animals, and dogs; however, repeat treatments may be necessary to eliminate parasites in reinfected farm animals. Currently used drugs in *Giardia*-infected humans are summarized in Table 1. The **control** and **prevention** of *Giardia* should be directed at young animals. They are highly susceptible to the parasite and show a markedly higher output of cysts than adult animals. Control measures for humans should be centered on environmental and personal ► **hygiene** issues such as routine hand-washing and control of insects to prevent their contact with infected stools. **Iodine** seems to be an effective disinfectant for drinking water; filtration systems are also recommended (drawbacks may be clogging and safe removal of contaminated filters); killing of *Giardia* cysts by boiling the water is most effective but will cost energy. The chances of a protective vaccine against giardiasis are poor.

Drugs Acting on Trichomoniasis in Humans and Cattle

► *Trichomonas vaginalis* (motile trophozoite) is a common pathogen of the urogenital system in men and women but is uncommon in

preadolescent girls. A frequent transfer of this flagellate is due to sexual intercourse, which explains the need for a therapy of both partners. In childbearing women, there may be an overall prevalence of 30 %, which is significantly higher than that in men (5 % or more). Very frequently, *T. vaginalis* infection is asymptomatic, especially so in the male. Clinical signs may develop if parasites cause degeneration and desquamation of the vaginal epithelium followed by inflammation of the vagina and vulva, and a leukocytic discharge may be evident. Topical treatment can be tried with clotrimazole or pimarinic but appears to be of little value because these drugs lack systemic action, which is essential in cryptic infection of men. Current **therapeutic drugs** with good systemic activity against *T. vaginalis* infections are the well-tolerated **5-nitroimidazoles** metronidazole, ornidazole, tinidazole, and others showing high cure rates even after a single dosing (Table 1). These drugs may differ somewhat in their pharmacologic properties but not so in efficacy or toxicity. They have a wide spectrum of activity, including ► *Entamoeba histolytica*, *G. lamblia*, *Balantidium coli*, and anaerobic bacterial infections. Drug resistance of *T. vaginalis* strains has been reported infrequently. This step forward in the 5-nitroimidazole therapy becomes apparent when comparing the list of more than 170 different treatment regimens with exotic compounds like picric acid and mercuric chloride cited in a book on trichomoniasis published about 50 years ago.

Also other flagellates may occur in the digestive tract or in the reproductive system being potential pathogens for diseases in mammals (monkeys, dogs, cats, zoo animals, or ruminants) and birds. ► *Tritrichomonas foetus* with three anterior flagella may be of significance in the veterinary medicine causing an ► **abortion** in cows followed by prolonged, and at times permanent, sterility or a closed pyometra (purulent endometritis). In the bull, the principal infection site is the preputial cavity. A *T. foetus* infection is transmitted during coitus or by artificial insemination and by gynecological examination of cows. The major control measure for trichomoniasis in cattle is the use of artificial insemination. The

Antidiarrheal and Antitrichomoniasis Drugs, Table 1 Drugs acting on *Giardia*, *Trichomonas*, amoebae, and *Balantidium* in humans

Disease Nonproprietary name (chemical group)	Brand name and other information	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments
Giardiasis <i>Giardia lamblia</i> may contaminate drinking water, which is a common source of infection for humans and mammals; flagellated trophozoites attach by their “suckers” to the surface of mucosa of the small intestine, producing partial villous atrophy of the duodenum or jejunum; the ovoid cyst is passed in feces and has a very distinctive form; although <i>G. lamblia</i> is commensal in many individuals, it may be particularly pathogenic in debilitated and immunosuppressed patients and is a common cause of diarrhea and a malabsorption syndrome characterized by excessive amounts of fat in the stool (steatorrhea) in travelers		
Metronidazole (5-nitroimidazole)	Flagyl, Clont, others	250 mg tid × 5 days; *15 mg/kg/day in 3 doses × 5 days (not licensed in the USA but considered investigational for this condition by the FDA)
Nitazoxanide	Alinia	500 mg bid × 3; *1–3 years: 100 mg q12 × 3 days; 4–11 year: 200 mg q12 × 3 days
Tinidazole (5-nitroimidazole)	Fasigyn, others	2 g once; *50 mg/kg once (max. 2 g) treatment should be followed by administration of iodoquinol or paromomycin in doses as used to treat asymptomatic amoebiasis (see below)
Furazolidone (nitrofuran)	Furoxone, others	100 mg qid × 7–10day; *6 mg/kg/day in 4 doses × 7–10 day toxic effects may be serious and common, hypersensitivity reactions (urticaria)
Paromomycin (aminoglycoside)	Humatin	25–35 mg/kg/day in 3 doses × 7 days (the use of drug may be suitable in pregnancy as it is not absorbed)

Trichomoniasis

Motile trophozoites of *Trichomonas vaginalis* can be found in the foamy vaginal discharge of trichomonal vaginitis; the creamy discharge is often secondarily infected with the yeast *Candida albicans*; infection is transmitted by sexual intercourse; asymptomatic infection in the male (and therefore not treated) may be often a source of trichomonal infection in the female partner; for this reason sexual partners should be treated simultaneously; metronidazole-resistant strains have been reported, and enhanced doses of the drug for longer periods or use of tinidazole may be effective against these strains

In cattle the *Tritrichomonas foetus* infection of the cow often leads to an abortion and sterility; infection is transmitted by coitus; in birds, particularly in pigeons, heavy *Trichomonas gallinae* infections may lead to high mortality caused by necrotic lesions in the mouth, crop, and the esophagus with extension to the bones of the skull, the liver, and elsewhere

Metronidazole (5-nitroimidazole)	Flagyl, Clont, others	2 g once; or 250 tid or 375 mg bid × 7days; *15 mg/kg/day in 3 doses × 7 days
Tinidazole (5-nitroimidazole)	Fasigyn, others	2 g once; *50 mg/kg once (max. 2 g) (the drug seems to be better tolerated than metronidazole, it is not marketed in USA)

Amoebiasis

Entamoeba histolytica infection occurs by oral uptake of cysts, which are quite refractory to environment; the cysts are ingested with drinking water or food, which is not readily prepared or thoroughly cooked; as the disease is not characterized by a certain incubation time, it is difficult to determine the onset of the amoebiasis; fever and feces containing blood and foamy fluid may be indications for acute amoebiasis; treatment should be started immediately after diagnosis has been made to avoid colonization of the liver by so-called “magna-forms” (tissue stages causing necrosis of liver parenchyma followed by formation of an abscess); large liver abscesses should be aspirated prior to treatment; there is no drug resistance in amoebiasis

(continued)

Antidiarrheal and Antitrichomoniasis Drugs, Table 1 (continued)

Disease Nonproprietary name (chemical group)	Brand name and other information	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments
Asymptomatic cases Asymptomatic carriers extruding cysts (quadrinucleate form) in the feces are an important source of infection; there are no therapeutic drugs, which may affect cysts; luminal drugs act directly (by contact) on (uninucleated) trophozoites of <i>E. histolytica</i> living in the lumen of large intestine; paromomycin may also act by modifying intestinal bacterial flora		
Diiodohydroxyquinoline (8-hydroxyquinoline)	Iodoxin, others (drug of choice)	650 mg tid × 20 day; *30–40 mg/kg/day (max. 2 g) in 3 doses × 20 day; toxic effect maybe SMNO (= subacute myelo-optic neuropathy) after high doses and for long periods
Paromomycin (aminoglycoside)	Humatin (drug choice)	25–35 mg/kg/day in 3 doses × 7 days (may be useful in pregnancy as it is not absorbed); *25–35 mg/kg/day in 3 doses
Diloxanide furoate (dichloroacetamide)	Furamide (alternative drug)	500 mg tid × 10 day; *20 mg/kg/day in 3 doses × 10 day remarkably safe drug for treatment of carriers
Mild to moderate intestinal disease Uninucleated trophozoites of <i>E. histolytica</i> invade the intestinal epithelium, principally in the cecum and the ascending colon, causing lytic necrosis of tissues; 5-nitroimidazoles are well absorbed from the intestine and exhibit a marked systemic effect on extraintestinal amoebiasis		
Metronidazole (5-nitroimidazole)	Flagyl, Clont, others (drug of choice)	500–750 mg tid × 10 day; *35–50 mg/kg/day in 3 doses × 10 day
Tinidazole (5-nitroimidazole)	Fasigyn (drug of choice)	2 g/day × 3 days; *50 mg/kg (max. 2 g) qd × 3 days (drug may be better tolerated than metronidazole; it is not marketed in the USA)
Ornidazole	Tiberal	2 g once a day × 3 days; amoebicidal activity of ornidazole is similar to that of other 5-nitroimidazole, not licensed in the USA
Severe intestinal disease, extraintestinal amoebiasis (hepatic abscess) In fulminating amoebic dysentery with loose feces, containing mucus and blood, the amoeba penetrate more deeply into the intestinal wall, thereby damaging all layers of the intestinal wall resulting in confluent ulceration; amoeba may pass into the lymphatics or mesenteric venules and invade other tissues of the body, especially the liver, but also skin or genital organs; the most common form is a large single abscess in the right lobe of liver		
Metronidazole	Flagyl (drug of choice)	750 mg tid × 10 day; *35–50 mg/kg/day in 3 doses × 10 day
Tinidazole	Fasigyn	2 g once daily × 5 days; *50 mg/kg/day (max. 2 g) × 5 days
Ornidazole (5-nitroimidazole)	Tiberal	2 g once a day × 3 days; amoebicidal activity of ornidazole is similar to that other 5-nitroimidazole; (not licensed in the USA)

Amoebic infections of central nervous system (CNS) and the eye

Free-living aquatic amoeba such as *Naegleria* spp., *Acanthamoeba* spp., and *Balamuthia mandrillaris* may cause various CN disorders, which may be fatal; *N. fowleri* causes a rapidly fatal infection known as “primary amoebic meningoencephalitis” (PAM); most patients with naeglerial infection have had a history of recent swimming in freshwater during hot summer weather; a number of *Acanthamoeba* species may produce a chronic CNS infection called “granulomatous amoebic encephalitis” (GAE) or an eye infection characterized by a chronic progressive ulcerative keratitis; *B. mandrillaris* also causes GAE; unlike naeglerial infection, GAE does not appear to be associated with swimming; infections are often seen in individuals debilitated or immunocompromised including patients with AIDS; diagnosis is made by microscopic identification of living or stained amoeba trophozoites in CSF (Giemsa-stained spinal fluid smears) or corneal scrapings, and motile amoeba (trophozoites) can be readily seen in wet-mount preparations; **chemotherapy** of PAM and GAE is problematic; almost all cases of PAM and GAE have been fatal because of the foudroyant course of PAM and lack of an effective causative treatment; considerable toxic amphotericin B seems to be the only drug with clinical efficacy

(continued)

Antidiarrheal and Antitrichomoniasis Drugs, Table 1 (continued)

Disease Nonproprietary name (chemical group)	Brand name and other information	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments
Amphotericin B (polyene antibiotic)	Amphotericin B powder	There are some known survivors of PAM , children from Australia, the UK, India, and the USA treated with amphotericin B: 1- (1.5) mg/kg/day $\times$ 3 days i.v. followed by 1 mg/kg/day $\times$ 6 days i.v. or longer (additional amphotericin B given intrathecally plus miconazole or rifampicin i.v.)
Miconazole	Daktar, solution for injection	GAE caused by <i>Acanthamoeba</i> has been successfully treated by total excision
Ketoconazole (azoles)	Nizoral	granulomatous brain tumor and administration of ketoconazole,
Flucytosine (pyrimidinone analog) various topical formulations of azoles and other drugs for <i>Acanthamoeba</i> keratitis	Ancobon	<i>Acanthamoeba</i> meningitis with penicillin, and chloramphenicol; <i>Acanthamoeba</i> and <i>Balamuthia</i> form cysts in tissues; thus, a potential effective drug for GAE must be capable of damaging cysts and trophozoites to prevent relapse after course of treatment; strains of <i>Acanthamoeba</i> isolated from fatal GAE cases were susceptible to pentamidine, ketoconazole, and flucytosine in vitro; today, <i>Acanthamoeba keratitis</i> can be managed by medical treatment alone, if diagnosis has been made soon enough; successful regimens may be topical propamidine, miconazole, and Neosporin with epithelial debridement (removal of infected tissue from the lesion to expose intact tissue) or clotrimazole, systemic ketoconazole, or itraconazole with topical miconazole and surgical debridement
Balantidiasis <i>Balantidium coli</i> (a ciliate) is a common commensal of the large intestine of wild and domestic pigs, but it can be pathogenic to humans and primates in which it produces various clinical forms (asymptomatic carrier condition, acute cases with fulminant diarrhea or chronic cases: diarrhea changes with constipation); however, human infections are infrequent and pigs act as the main reservoir for human infections; motile flagellated trophozoites can invade the submucosa of the large intestine, causing an ulcerative enteritis in severe cases; trophozoites and cysts are passed in the feces and can readily be found in fresh wet-mount preparations; the main endemic areas are in the tropical and subtropical areas and where there is close contact between humans and pigs; humans become infected by ingestion of cyst-contaminated food and water		
Tetracycline (tetracyclines)	Various	500 mg qid $\times$ 10 day; *40 mg/kg/day (max. 2 g) in four doses $\times$ 10 day; the use of tetracyclines is contraindicated in pregnancy and children <8 years of age; they discolor teeth in growing children; (not licensed in the USA but considered investigational for this condition by the FDA)
Metronidazole (5-nitroimidazole)	Flagyl (drug of choice)	750 mg tid $\times$ 5 days; *35–50 mg/kg/day in 3 doses $\times$ 5 days (not licensed in the USA but considered investigational for this condition by the FDA)

(continued)

Antidiarrheal and Antitrichomoniasis Drugs, Table 1 (continued)

Disease Nonproprietary name (chemical group)	Brand name and other information	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments
Diiodohydroxyquinoline (8-hydroxyquinoline)	Iodoxin alternative drug	650 mg tid × 20 day; *40 mg/kg/day in 3 doses × 2 day (not licensed in the USA but considered investigational for this condition by the FDA)

Abbreviations: Letter *d* stands for day (days); *qd* daily (quaque die), *bid* twice daily, *tid* three times per day, *qid* four times per day (quarter in die), *pc* (post cibum) after meals

Dosages listed in the table refer to information from manufacturer or literature (e.g., Medical Letter 46, 2004)
Data given in this Table have no claim to full information

administration of **5-nitroimidazoles** like metronidazole or tinidazole is probably the most effective and expensive therapy for most of these protozoan infections. However, in some countries the use of 5-nitroimidazoles in food animals is now subject to regulatory actions of government agencies. The aim is to remove drugs of this chemical group from the market because of potentially cancerogenic action in rodents. Benign epithelial tumors (adenoma) have been observed in mice after being treated with high daily doses of metronidazole and others 5-nitroimidazoles administered for prolonged periods such as 6 months or so.

Drugs Acting on Histomoniasis (Blackhead Disease) of Birds

Histomonas meleagridis is found in the ceca and liver of various birds (turkey, chicken, peafowl, guinea fowl, pheasant, partridge). The organism is probably transmitted by ingestion of cysts and/or anal contact to fresh feces. The amoeboid stage of the flagellate may cause enterohepatitis in turkeys (or chickens) under range or yard management and thus high economic losses in the turkey industry. Control of enterohepatitis consists of good husbandry and preventive medication; contact between turkeys and chickens must be avoided, and regular treatment of all birds with anthelmintics should be performed to reduce the incidence of *H. gallinarum*, which apparently suppresses the immune system. Drugs used as additives in feed and/or therapeutic drugs in water belong to different chemical groups. Various **5-nitroimidazoles** such as dimetridazole, ronidazole, carnidazole, or

ipronidazole may be used in feed (the latter drug at dose levels between 50 and 85 ppm, withdrawal time 6 days, EC directives, 1999). Nifursol (use level in feed, 50–75 ppm, withdrawal time 5 days, EC directives, 1999) or furazolidone and others belong to the group of **5-nitrofuranes**. However, in various countries, there are increasingly legislative restrictions concerning the use of additives in feed for the prevention of histomoniasis because of potential cancerogenicity of these drugs in rodents.

Drugs Acting on Intestinal and Extraintestinal Amoebiasis of Humans

Entamoeba histolytica in humans, monkeys, dogs, cats, and zoo animals may produce acute or chronic enteritis associated with profuse and heavy diarrhea. Acute ► **amoebiasis** must be differentiated from the chronic form. The use of amoebicidal drugs in the treatment of patients with various clinical forms of amoebiasis (Table 1) has contributed to reduction of ► **morbidity** and mortality of the disease. Luminal drugs are used to treat asymptomatic carriers passing cysts of *E. histolytica* in stool being an important source of infection. Various drugs are available for patients with invasive intestinal amoebiasis associated with ulceration of deep layers of the intestinal wall of the cecum and colon (Table 1). The same agents (e.g., 5-nitroimidazoles) can be used in treating invasive extraintestinal amoebiasis, involving the liver, skin, and other organs. Systemic amoebicides currently seldom used because

of their high toxicity or only limited action (e.g., chloroquine) are emitine and dehydroemetine (alkaloids), which acts in the liver, and intestinal wall (other tissues), and chloroquine, which acts in the liver only. Emitine and dehydroemetine administered intramuscularly are fairly toxic drugs producing cardiac arrhythmia, and asystole, but also adverse effects of the central nervous system (CNS).

Drugs Acting on Amoebic CNS Diseases and Amoebic Keratitis

A number of free-living opportunistic ► **amoebae** are known to be potential pathogens for humans. *Acanthamoeba* spp., ► *Balamuthia mandrillaris*, and ► *Naegleria fowleri* can cause lethal infections particularly in children having close contact with water. Their distribution is worldwide in freshwater and soil. The protozoans live preferably in aquatic habitats where they feed on bacteria (e.g., in warm lakes or swimming pools). Infection by *N. fowleri* is acquired by intranasal absorption of amoebae (flagellates or cysts); trophozoites invade the nasal mucosa, cribriform plate, and olfactory bulbs of the brain (cysts are absent in infected tissues). *Acanthamoeba* spp. and *B. mandrillaris* may infect man via nasal mucosa, causing fatal CNS disease or by direct invasion of the cornea through lesions of the eye or the wearing of contaminated contact lenses of healthy persons, producing *Acanthamoeba* keratitis. Primary amoebic meningoencephalitis (PAM) due to *N. fowleri* is usually diagnosed after death of patient and is characterized by an acute, hemorrhagic, necrosing meningoencephalitis. *Acanthamoeba* spp. and *B. mandrillaris* cause focal granulomatous amoebic ► **encephalitis** (► **GAE**), and trophozoites and cysts occur in most infected tissues. **Chemotherapy** of PAM and GAE is problematic, and only a few cases have been treated successfully with the highly toxic polyene antibiotic amphotericin B (Table 1). *Acanthamoeba* keratitis, which increasingly occurs in immunocompromised patients, can be treated with success if it is diagnosed at an early stage. Various drugs (dibromopropamide,

neomycin azoles, alone or in combination) have been administered topically as ointments and drops (see Table 1).

Drugs Acting on Balantidiasis

► *Balantidium coli*, which possesses ► **cilia** for locomotion, is a natural inhabitant of the digestive tract of mammals and widespread in swine; the vegetative forms of *Balantidium* (man, monkeys, and pigs) may produce acute or chronic enteritis with profuse and heavy diarrhea. Good hygiene and sanitation may prevent infections, which are associated with close contact to pigs. Acute *B. coli* infections may be treated with **tetracycline**. Alternative drugs may be the 5-nitroimidazole **metronidazole** (Table 1). In many countries its use in food animals is now subject to regulatory actions of government agencies; the aim is to remove drugs of this chemical group from the market because of their potentially cancerogenic action in rodents after prolonged administration.

Antifolates

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Drugs acting against folate production, e.g., in malaria parasites (► **malariacidal drugs**).

Antigen

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *anti* = against; *gennan* = produce.

This term describes a product/compound produced by parasites or other agents of disease, which is recognized by the immune system of a host. In general, antigens represent high molecular proteins, glycoproteins, glycolipids, etc.

Antigenic Variation

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Anti = against; *gennan* = produce, initiate; Latin: *varietas* = variation.

This term describes the ability of several parasites to produce several antigens/layers on their surface so that the host has problems to produce as quick new ► [antibodies](#) against the foreign components. For example, trypanosomes are able to produce different variant surface glycoproteins at short intervals; ► [VSG](#).

compound – that induce the production of antibodies and bind to antibodies. Parasites may present a great quantity and variety of antigens to the host that change with time as a consequence of maturation through different life-cycle stages. Parasitic antigens may be divided into several categories: diagnostic, protective, and pathologic. An antigen acts as immunogen when it is able to induce an immune response (immunogenicity). In general, different antibodies are produced to an antigen which bind to different epitopes. The hosts' immune response depends on the presentation, quantity, and kind, of ► [circulating antigen](#). Cross-reacting epitopes exist between the different stages of the same species and between different species of the same genus. In ► [helminth](#) infections there is a high degree of cross-reactivity between species and genus. The antigens of helminths commonly exposed to the immune system are excretory and/or secretory (E/S) antigens or surface molecules (somatic antigen). Antigens of ► [protozoa](#) have a lower degree of variability between species, and their immunogens are mainly surface antigens. For each parasite the diagnostic potency of surface, E/S, and somatic antigens has to be evaluated in regard to their effectiveness in a specific test system.

Antigens

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Immunogens

Introduction

Antigens are molecules – proteins, peptides, carbohydrates, nucleic acids, lipids, or any other

Antigen Processing

Due to the often complicated life cycle of parasites, including vector transmission, it may be difficult to maintain helminth parasites in laboratory animals or in vitro. In practice it is impossible to recover large quantities of antigen from each pathogen species. It is a common laboratory practice to select one single, highly cross-reacting species for antibody screening within a whole genus (► [Brugia malayi](#) for filariasis, *Schistosoma mansoni* for schistosomiasis, *Leishmania donovani/infantum* for leishmaniasis, and *Plasmodium falciparum* for ► [malaria](#)). Until recently the primary source of antigen for most of the serological assays was parasite maintained in vivo (helminths) or in continuous in vitro culture systems (protozoa). Complete cells,

fragments, or cryosections of parasites (cellular antigens) are used as antigen in IFAT, DT, and agglutination test. Crude or purified soluble extract antigens or culture-derived E/S antigens are utilized in other test systems like ► [ELISA](#), IHAT, CFT, CIEP, and gel precipitation. Today, new technologies which allow the construction of synthetic peptides, recombinant proteins, or DNA-based immunization have opened up the possibility for large-scale production of defined antigens or specific antibodies. However, for each preparation the diagnostic potency must be proven. It could be shown that a single antigen or a monoclonal antibody may be satisfactory for individual diagnosis but not for screening purposes. A combination of several defined antigens may improve the sensitivity, a polyclonal antibody, the binding capacity of a test system.

Antigen Assays

Immunoassays for antigen detection are increasingly developed. Urinary antigen detection is of diagnostic interest for parasites with developing stages associated to the genitourinary tract (► [Schistosoma haematobium](#), ► [Trichomonas vaginalis](#)) or parasitic antigens excreted during the acute or ► [chronic infection](#) stage in urine (► [Wuchereria bancrofti](#), [Trypanosoma cruzi](#)). Circulating antigen detection is useful for a quantification of blood parasites (► [Trypanosoma](#) spp., microfilariae) or detection of E/S antigens (► [Schistosoma](#) spp.). It may provide information on the presence and/or activity of the parasite. Antigen detection in stool specimens enables a species-specific diagnosis which is impossible after microscopic examination ([Entamoeba histolytica/dispar](#), ► [Echinococcus](#) spp.).

Clinical Relevance

Many stage-specific antigens of different parasites have been characterized so far and some of them are already applied in serodiagnostic test systems.

A tachyzoite-specific, recombinant surface antigen (P30) is of proven diagnostic value for the detection of *Toxoplasma* antibodies. Species-specific antigens of *Echinococcus multilocularis* like Em18 or the recombinant antigen Em2 are in use for the serological differentiation of infection with the alveolar or cystic form. ELISAs with improved specificity by use of recombinant antigens were developed for parasitic infections like Chagas' disease, leishmaniasis, ► [Strongyloides](#), and many others. Defined glycoproteins of the cyst fluid from ► [Taenia solium](#) are highly specific and allow the identification of patients with ► [cysticercosis](#) by use of the WB. The seroreactivity to a specific antigen as indication for active infection was described for ► [visceral leishmaniasis](#) and amebiasis. The detection of one or both genus-specific *Schistosoma* antigens (circulating anodic, CAA, and cathodic, CCA, antigens) indicates an active schistosomiasis. A positive correlation between *Schistosoma haematobium* egg excretion and levels of CAAs was reported. The level of complexed antigen in serum is a good indication for the microfilarial load in ► [bancroftian filariasis](#).

Not only a quantification of the parasite load but also a discrimination between recent and past infection is possible by urinary antigen detection. A better discrimination between acute and congenital-infected patients was reported for Chagas' disease. The immunodiagnosis of intestinal parasitic infection has advanced significantly through the development of coproantigen detection methods. Commercial ELISA systems which use monoclonal antibodies for the detection of fecal parasitic antigens like *E. histolytica/dispar*, *Giardia lamblia*/*G. intestinalis*, and/or *Cryptosporidium* spp. are now available and are going to replace microscopic examination in many laboratories. However, the specificity, sensitivity, and clinical value of the available tests are still under investigation. The detection of *Echinococcus* antigen in fecal samples of the dog (*E. granulosus*) or fox (*E. multilocularis*) by use of polyclonal antibodies may become an important diagnostic tool in veterinary medicine.

Oxidative damage is one of the most relevant
pathological effects in human *Plasmodium* infec-
tions as well as in other parasitoses. Therefore, a
number of known antioxidants, such as vitamins
C and E, desferroxamines, folate,
N-Acetylcystein, etc., have been tested.
Some promising results are collected in Table 1
by Isah and Ibrahim (2014) and should
stimulate for further research in antiparasitic
compounds.

Antioxidants, Table 1 Effects of different antioxidants on *Plasmodium* infections and its associated oxidative damage

Antioxidant	<i>Plasmodium</i> species	Effect on parasitemia	Effect on oxidative damage
Vitamin E	<i>P. berghei</i>	NE	↓
Vitamin C	<i>P. berghei</i>	ND	↓
	<i>P. falciparum</i>	↑	↑
	<i>P. falciparum</i>	NE	ND

Apathogenic Trypanosomes (Stercoraria)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *trypanon* = boring system, *soma* = body; *theileri* = Arnold Theiker (1867–1936), South African veterinarian; *mel* = honey; *phagein* = feeding; *theodori* = Theodor, scientist; Greek: *sterx* = posterior end; *korax* = hook.

Geographic Distribution/Epidemiology

These three species belong to the group of so-called Stercoraria. They are found worldwide, in Europe rare. Since they are mostly harmless, there are no reports on epidemics; also high prevalence rates are described.

Morphology/Life Cycle

(a) *Trypanosoma theileri* (Fig. 1): These parasites occur in cattle, reach a length between 31 and 64 μm and are characterized by a bended shape, a very long, pointed posterior end and a large, centrally situated marginally and close to the nucleus (not at the posterior end as in other trypanosomes). Vectors are tabanids, biting flies and probably ixodid

Apathogenic Trypanosomes (Stercoraria), Fig. 1 Light micrograph of a Giemsa stained trypomastigote stage of *T. theileri* in the blood of a cow. Note the typical positions (bars) of the nucleus and the kinetoplast plus attachment site of the flagellum

ticks. In Germany, mostly apathogenic. Species reaches prevalence rates of up to 60 %.

- (b) *Trypanosoma melophagium*: This species occurs in the blood of sheep and reaches a length of 40–60 μm . Vectors are sheep lice (*Melophagus ovinus*) which were ingested orally by the sheep. Transmission also occurs by ingesting feces of vectors.
- (c) *Trypanosoma theodori*: This parasite was found in goats in the Western countries of Asia, is pathogenic, and becomes transmitted by feeding infected lice flies (*Lipoptena caprina*) or their feces.

Symptoms of Disease

Mostly apathogenic. However, under stress the infected animals may show slight symptoms in case they are kept under stress conditions.

Diagnosis

Microscopic demonstration in stained blood smears (after concentration). Diagnosis is also possible by help of ► [xenodiagnosis](#), when uninfected vectors are placed in bags onto the skin of potentially infected animals.

Infection

The hosts of all three species are primarily infected by feces containing parasites. Transmission is also possible by feeding feces of vectors, by feeding infected vectors or even by passage of trypomastigotes to the fetus when wandering through the placenta of pregnant animals.

Prophylaxis

Use of insecticides.

Incubation Period

Unknown, this is mostly asymptomatic.

Prepatent Period

Unknown.

Patency

Apparently years.

Therapy

Not necessary.

Apicomplexa

Synonyms

Sporozoa

Classification

Subphylum of ► [Alveolata](#) (new system), Phylum of ► [Protozoa](#) (old system).

General Information

Members of this phylum are characterized by the occurrence of the name-giving sporocysts (and/or oocysts) which produce the infectious sporozoites. The life cycles comprise a regular alternation of different sexual and/or asexual generations (► [Coccidia](#)). Although several multinucleate stages occur during the reproduction of individuals of the different species (► [Plasmodium](#)/Fig. 2), the typical sporozoan cell is uninucleate. With respect to fine structure the Sporozoa are a relatively uniform group, being provided with a typical ► [apical complex](#) (► [Pellicle](#)/Figs. 3, 4, and 5).

System

Due to these fine structural features, several groups of parasites have been added to, or excluded from, the Sporozoa. This led to the systematic concept of Levine et al. which is, however, not generally accepted. Thus, the authors of this chapter do not support the addition of the class Perkinsea, since the fine structure is not identical with that of other sporozoans. Furthermore, we find it necessary to include the ► [Piroplasma](#) (► [Babesia](#)/Fig. 1, ► [Theileria](#)/Fig. 1) and all blood-parasitizing members of the ► [Adeleidea](#) (genera *Karyolysus*, ► [Hepatoozon](#), *Haemogregarina*, ► [Leucocytozoon simondi](#)/Fig. 1, ► [Karyolysus lacertae](#)/Fig. 1, ► [Hepatoozon](#)/Fig. 1) in the Haemosporida. Thus, in our opinion the following system better

Apicomplexa, Fig. 1 Overview of groups among Sporozoa (Apicomplexa/Alveolata) (according to Mehlhorn and Schein). Recent molecular biologically obtained data indicate that it is necessary to exclude *Toxoplasma*, ► *Sarcocystis*, and ► *Isoospora* from Eimeriidae

and to include them into a newly created sister family (Sarcocystidae). Furthermore Perkinsea are surely no longer Apicomplexa but dinoflagellates. The genus *Cryptosporidium* probably belongs to the group of Gregarines

reflects the biological and morphological relations among the members of the Sporozoa (Fig. 1).

Surface Coat

The major surface proteins of ► *Plasmodium* merozoites or ► *Toxoplasma gondii* ► tachyzoites have been shown to be GPI-anchored (► *Glycosylphosphatidylinositols*). The Circumsporozoite protein (► *CSP*) of sporozoites and the ► *ookinete* surface proteins have the primary sequence requirements for ► *GPI* anchoring, although the latter has not been formally demonstrated due to the low amount of material available for study. Although the trimannosylglucosaminyl core is common with kinetoplastids, the structure of the GPI anchors differs from the trypanosomes, and among apicomplexans, by the sugar ornamentation of the glycannic core, and it does not undergo remodeling after addition to the protein.

The GPI anchor of *Plasmodium* has been shown to be a strong immunomodulator responsible for signal transduction in cells of the vertebrate host.

The MSP1 of *Plasmodium* merozoites undergoes proteolytic processing before reinvasion, and shedding of the cell coat described during invasion coincides with the removal of most of the protein except the C-terminal 19 kDa that is internalized with the parasite inside the red blood cell. In sporozoites, the CSP is deposited on the substrate during motility on serum albumin-coated surfaces, or is capped and shed when bound to specific antibodies. The mechanism of shedding (release of proteins, cleavage of the anchor, or removal of lipids associated with the coat) is not elucidated. As described below, the contribution of GPI-anchored proteins to Apicomplexan motility is not known; in addition, exocytosed microneme protein are transiently inserted into the ► *plasmalemma* of the parasites during motility and at the invasion stage and may therefore be part of the glycocalyx during a short period of the parasite cycle.

Motility

As described by many investigators, motility of Apicomplexan zoites can be subdivided into three

types which are, respectively, gliding, twisting, and bending. Only the first type leads to active displacement of the ► **zoite**, the two others being involved in changing the direction of motion. Gliding motility is very uncommon among eukaryotic cells; it is clearly different from amoeboid locomotion and involves a unique molecular assembly of proteins originating from several compartments of the zoite.

In all cases, gliding motility has been described as the backward translocation of a “junction” between a substrate and the zoite surface along the latter’s longitudinal axis. The substrate could be detected by small latex beads which, in the case of the gregarine, were translocated and accumulated at the posterior extremity of the organism. The experiments clearly demonstrated that the gliding motility of Apicomplexan zoites was a relative phenomenon in which the moving partner could be the zoite or the substrate depending on their respective size. Physiological studies of these models and others have shown that gliding was temperature- and cytochalasin D-sensitive, this last property being interpreted as a clue to the participation of ► **actin** in zoite motility. Indeed, in *T. gondii*, the direct involvement of actin in motility has been demonstrated and ► **myosin** is also implicated, both molecules being found between the plasmalemma and the inner complex of zoites.

The parasite surface molecules involved in motility are essentially derived from the exocytosis of micronemes. Indeed, the resident surface proteins being GPI-anchored, they cannot transduce directly a mechanical force originating from the acto-myosin motor located below the plasma membrane. Instead, transmembrane proteins initially located in micronemes are translocated on the parasited surface by exocytosis at the parasite apical area and operate this transduction. Very elegant genetic studies in *P. berghei* have demonstrated the critical role of a highly conserved microneme protein TRAP in the gliding motility of sporozoites. These findings, together with other investigations in *T. gondii* have led to the description of the molecular assembly responsible for gliding motility. The TRAP family proteins are inserted into the plasma membrane and their

cytoplasmic C-terminus sequence interact via an aldolase and triggers the polymerization of short actin filaments that are propelled by resident myosin molecules that are attached to underlying inner membrane complex. This antero-posterior translocation of a transmembrane protein interacting with the substrate via its N-terminus is responsible for the gliding motility (Fig. 2).

The nature of the interaction between the zoite and the substrate is entirely unknown. A classical receptor-ligand interaction is unlikely since gliding motility has also been observed on glass or on liquid-liquid interfaces and it thus appears that zoites may use physical properties of interfaces and surface tension to interact with substrates.

The ► **orientation** of motility, along the zoite axis, and its exclusive forward directionality can be related to morphological characteristics of zoites, although no experimental demonstration of a relation between structures and motility has yet been obtained. Indeed, freeze fracture has demonstrated highly organized structures within the ► **pellicle** of Apicomplexan zoites: although the outer layer (cytoplasmic membrane) shows little differentiation, the inner membrane complex, which is made of two closely apposed membranes underlying the plasmalemma, is highly organized. This inner complex is in fact a continuous layer of rectangular flattened vesicles (plates) arranged in longitudinal rows except at the anterior extremity where a truncated conical plate (Apical Cap) is found (Fig. 3). The intramembranous particles of both membranes of the inner complex are arranged in a dense array of parallel longitudinal lines. Lines of higher particle density are found over the subpellicular microtubules which extend longitudinally under the inner complex (Fig. 4). Similar structures have been observed in all Apicomplexan zoites described so far. This highly organized longitudinal pattern is likely to provide the template for the translocation of the TRAP Proteins. A correlation between these morphological features and the actomyosin motor of motility remains to be established.

Another phenomenon has been described on apicomplexan zoites which also concerns the surface interactions between these organisms and their surroundings. When zoites are presented

A

Apicomplexa, Fig. 2 Schematic drawing of the mechanism of zoite motility in Apicomplexa. The myosin motor (myoA motor complex) is associated with the inner membrane complex, oriented by the subpellicular microtubules. Microneme proteins become inserted in the plasmalemma

and associate with short actin filaments through an aldolase. The actin-aldolase-microneme protein complexes are translocated by the myosin motor while interacting with the substrate, resulting in gliding motility (After Soldati and Meissner 2004, modified)

Apicomplexa,

Fig. 3 Freeze fracture replica of second generation merozoites of the chicken

► *Coccidia Eimeria necatrix*. Three fracture planes are found in the ► pellicle, corresponding to the three membranes (e plasmalemma, m and i inner membrane complex). The inner membrane complex is made of continuous rows of longitudinal plates containing longitudinal arrays of intramembranous particles (bar = 1 µm; Dubremetz and Torpier, original)

with a variety of ligands interacting with their surface (cationized ferritin, surface antigen-specific antibodies), they are at first entirely covered with the ligand but they are able to cap it on their posterior extremity and shed it into the medium. This ► capping phenomenon shares many common features with gliding motility (polarity, temperature, and cytochalasin

D sensitivity) although, as mentioned above, the way GPI-anchored proteins can be moved by the actomyosin motor is unknown.

If one considers motility of parasites as the way of homing to their host (host cell in the present case), one would then wonder whether any signal or tropism guides the zoite to its definitive location, which is usually extremely specific. No such

Apicomplexa, Fig. 4 Schematic diagram of the organization of the ► **pellicle** of Apicomplexan zoites as revealed by freeze fracture. Three fracture planes lead to three pairs of complementary fracture faces named according to the conventional nomenclature (*E* external face,

P protoplasmic face). Longitudinal arrays of intramembrane particles are found in the *P* faces of the inner membrane complex; lines of higher particle density overlay ► **subpellicular microtubules** (*e* plasmalemma, *m* and *i* inner complex, *t* microtubule)

phenomenon has been described so far concerning Apicomplexans and in most cases, homing to the vicinity of the target cell seems to be passive; the zoites being driven either by the digestive or the circulatory route depending on the inoculation site. Gliding motility seems to be operational within a short range and to allow accidental contact between zoite and host cell when the organism has been passively carried close to the site of interaction. In the case of malaria sporozoites, the high specificity of recognition between hepatocyte surface proteoglycans and parasite surface proteins seems to be a major cause of organ targeting, probably by inducing binding of sporozoites to the hepatocytes when they are carried in the vicinity of these cells by the bloodstream.

Host Cell Recognition

Regarding the host cell recognition process, two groups seem to exist among Sporozoa: one in which a highly specific recognition step occurs which concerns the blood parasites (Hemosporidia, ► **Piroplasms**), and another in which little if any specific recognition of the host

cell concerning the Coccidia can be demonstrated. This difference is better understood when one realizes that a *Plasmodium* ► **merozoite** is only able to invade the red blood cells of an extremely narrow range of hosts whereas a *T. gondii* tachyzoite readily invades almost any type of cells it gets in contact with. The difference between the two groups could also be interpreted as the need for receptor-ligand-mediated adhesion as a prerequisite to invasion by blood parasites whereas this step would be unnecessary to Coccidia whose host cell and tissue specificity in situ could be due to other mechanisms. However, another possibility is that binding always occurs before invasion but its specificity varies depending on the parasite and allows a variable range of invasion that may or may not need further specific interaction to determine development or escape and search for a more suitable host cell. Although the surface proteins of the invasive stages seem to be involved in the recognition binding to the host cell, the ► **micronemes** proteins which are translocated on the surface of the parasite appear to be essential in parasite–host cell interaction in all Apicomplexa. The present status of knowledge does not clearly differentiate

between recognition binding and motility of Apicomplexan zoites.

In the case of blood parasites (*Plasmodium*, ► *Babesia*), receptor–ligand types of interaction have been shown to occur between zoites and erythrocytes. These events seem to be involved in the adhesion of the parasite to its target cell which holds the partners together after accidental contact and allows invasion to proceed. Phase contrast microscopic observations of red blood cell invasion by merozoites of *P. knowlesi* or *P. falciparum* have shown that initial contact could occur between any two points of the surfaces of the two cells. Then the merozoite reorients itself in such a way that its apical end faces the erythrocyte membrane. ► **Moving junction** formation and invasion then occur. Reorientation has been suggested to be effected by a gradient of receptors directed towards the apical end of the zoite. The respective part of receptor-mediated interaction in initial contact, reorientation, and moving junction formation is still unclear because of the difficulty of manipulating these different events in vitro. Thus the following applies to these interactions as a whole and we will only describe the *P. falciparum* model.

Recognition events concern interactions between merozoite receptors and erythrocytic ligands. Soluble molecules acting as bridges between both surfaces may also be involved. Most of the data obtained on these interactions come from in vitro experiments in which a *P. falciparum* culture was subjected to various treatments (use of variant red cell phenotypes, enzymatic alteration of erythrocyte surface, competition with soluble molecules) or from affinity of parasite molecules for erythrocytes (erythrocyte-binding antigens) or erythrocyte fractions (Glycophorin).

Concerning the erythrocyte, Glycophorin A (major sialoglycoprotein) is the major ligand in interaction with merozoites. More precisely, O-linked sialylated polysaccharides of the molecule seem to be directly involved in recognition. However, in addition, sialic acid-independent recognition and invasion can occur in certain strains, which suggests the existence of alternate

pathways allowing the parasite to survive if one way fails to operate.

The main merozoite receptors described so far are molecules having affinity for the erythrocyte surface that were initially described as ► **erythrocyte-binding antigens (EBA)**. These molecules are located in micronemes and are translocated in a transmembrane orientation on the merozoite surface where they play a major role in host cell recognition-invasion. A highly conserved family of ► **EBA** proteins expressed in the merozoite stages of various *Plasmodium* has been characterized; they all contain a conserved N-terminal cystein-rich domain that is involved in recognition. As for most microneme proteins, the way these proteins stored in the lumen of an organelle become transmembrane in the parasite surface is unknown.

Although *P. knowlesi* shares a part of its erythrocyte host range with *P. falciparum*, the recognition events seem to be distinct from the ones involved for the latter species. The Duffy blood group antigen has been described to play a key role in *P. knowlesi* invasion, in association with the DBL, which is a member of the erythrocyte-binding ligands EBL. The Duffy antigen is also involved in *P. vivax* invasion.

The role of ► **merozoite surface proteins** in erythrocyte invasion is unclear; the major merozoite surface protein (MSP1) may participate in initial binding, and antibodies that inhibit its proteolytic cleavage occurring during invasion block cell entry, but the receptor for this interaction is unknown. This surface protein may be acting as an early ligand of low affinity that allows close contact between both partners and is then strengthened by the EBL–glycophorin interaction.

Whether the receptor-ligand recognition that precedes invasion is maintained in the moving junction that powers invasion is unknown; however, observations on the interaction between *P. knowlesi* and Duffy negative red cells where the junction does not form suggest that the DBL protein may be involved in the junction.

In the ► **sporozoite** stage of the malarial parasite life cycle, receptor-ligand recognition has been postulated to drive the interaction with the

target cell, which is the hepatocyte. Although *Plasmodium* sporozoites have been shown to invade a rather large range of cells in vitro, their very efficient homing to the hepatocytes in vivo is probably driven by the affinity between the circumsporozoite surface protein CSP and the hepatocyte surface heparan sulfate proteoglycans.

Another system of recognition, which is found in *Plasmodium* sporozoites and is conserved in many Apicomplexa is the ► **TRAP** microneme protein family. In *Plasmodium* sporozoites, this protein also binds sulfated sugar-containing domains on the hepatocyte surface. *Toxoplasma gondii* and *Eimeria tenella* contain TRAP-like proteins in their micronemes, but their putative receptors have not been identified.

Micronemes of *T. gondii*, *Cryptosporidium*, and *Sarcocystis* also contain proteins with cell-binding properties, some of which with lectin features, that probably play a role in host cell recognition, although yet unidentified.

Host Cell Invasion

Due to their medical significance, ► **host cell invasion** by Apicomplexan zoites has mainly been studied with malaria parasites and *T. gondii* to a lesser extent with the Coccidia and *Eimeria*, *Sarcocystis* or with piroplasms.

In all cases in which invasion has been described in detail, Apicomplexan zoites enter the host cell apical end first, i.e., the area where the so-called apical complex is located and especially where the rhoptry ducts reach the zoite membrane. The zoite then gains access into an intracellular compartment surrounded by a membrane which is continuous with the host cell plasmalemma during invasion. The fate of that membrane has long been controversial since some authors have described its disintegration during the invasion, arguing that the ► **parasitophorous vacuole** appeared later around the cytoplasmic parasite. These conclusions were based on preparation artifacts due to the peculiar nature of the developing parasitophorous vacuole membrane which is poorly stabilized by the electron microscope preparation.

A very precise description of invasion has been given for *P. knowlesi*, this species being more amenable to experimental study of invasion than any other malarial parasite because of the relatively long shelf life of its merozoites. The initial step of internalization is a close contact between the apical end of the merozoite and the red blood cell plasmalemma. This latter becomes thicker on its inner side under this contact. Initiated as a segment of a sphere, this “junction” turns into a ring which moves backward on the zoite surface, whereas the host membrane area previously involved in the junction becomes the developing parasitophorous vacuole. The ring travels along the zoite to its posterior end where the junction ends up as a segment of a sphere, at which level the vacuole closes and separates from the host plasmalemma. The ► **surface coat** of the merozoite has been shown to be “shaved off” at the level of the junction as this latter went along the zoite surface.

Associated with this process are the formation of vesicles facing the zoite apex on the cytoplasmic side of the developing parasitophorous vacuole, and a clear decrease in the electron density of the rhoptry contents. The ► **rhoptries** open at the tip of the zoite and their contents are in contact with the parasitophorous vacuole membrane. Freeze fracture electron microscopy has shown a total depletion of intramembranous particles of the developing parasitophorous vacuole compared to the erythrocyte plasmalemma, which indicated a very low proteinic content for this membrane. A second observation was that the moving junction had a peculiar freeze fracture structure as a rhomboedric network of “particles” in the erythrocytic side, which indicated that the junction was more than a close apposition of membranes but that the internal structure of the host ► **cell membrane** was altered at this level.

From a physiological point of view, the major finding was that cytochalasin D inhibited the invasion, although the junction was initiated at the apex of the zoite and some vesicles appeared on the cytoplasmic side of the junction indicating that the actin motor was not needed for junction formation and rhoptry exocytosis, but essential for entry. Protease inhibitors were also found to block

Apicomplexa,

Fig. 5 Invasion of a mouse reticulocyte (*R*) by a merozoite of *Plasmodium yoelii nigeriensis* (*c* merozoite cell coat, *m* moving junction, *pv* developing parasitophorous vacuole, *bar* = 0.2 μ m; courtesy of G. Prensier, original)

A

the phenomenon, which suggests that proteases may be involved in the process.

► **Host cell invasion** by Coccidia has been studied both in vitro and in vivo. Because of the larger size of the zoites and the more complex organization of the host cells, the results obtained by electron microscopy were not as clear as for *Plasmodium*. Moreover, the host cells chosen for experimental studies were in some cases professional phagocytes (monocytes, macrophages), which raised additional questions concerning the active part played by zoites in entry. It is now clearly demonstrated that host cell invasion by Coccidia proceeds as described for *Plasmodium*, i.e., by a moving junction gliding backward on the zoite which enters a parasitophorous vacuole, the membrane of which is continuous with the plasmalemma of the host cell but depleted of intramembranous particles (Figs. 5, 6, and 7). The freeze fracture features of the moving junction are identical to the ones found on red blood cell membranes in *Plasmodium*.

Abundant membrane whorls are found in the parasitophorous vacuole or in “empty rhoptries” and vesicles are found on the cytoplasmic side of the parasitophorous vacuole, especially when invasion is blocked by cytochalasin, these vesicles contain rhoptry proteins.

Thus, the invasion process is conserved in all intracellular Apicomplexa, characterized by a moving junction and the development of the parasitophorous vacuole. The moving junction components have been recently identified in *T. gondii*: it contains proteins exocytosed from both the micronemes (AMA1) and from the anterior part of the rhoptries (rhoptry neck, RON proteins). These proteins are associated in a transmembrane complex at the junction level. This complex is believed to be moved by the parasite actomyosin motor on the parasite side, and to attach to host cell receptors or cytoskeleton. Another possibility is that the complex itself is anchored in the host cell membrane, avoiding the need for a specific receptor. A schematic view of the invasion process is shown in Fig. 8 (page 111).

The origin of the parasitophorous vacuole membrane is still controversial. The respective contributions (qualitative and quantitative) of the host cell plasma membrane and of rhoptry products are not fully determined, although both are probably involved. Ward et al. using fluorescent lipids or electrophysiological procedures, have shown in both *P. knowlesi* and *T. gondii* that host cell membrane components (essentially lipids) contribute a major part of the early parasitophorous membrane.

Apicomplexa,

Fig. 6 Invasion of HeLa cell (*H*) in vitro by a tachyzoite of *Toxoplasma gondii* (*R* rhoptry, *eR* empty rhoptry, *N* nucleus, *m* moving junction. *bar* = 1 μ m; Ferreira and Dubremetz, original)

**Apicomplexa,**

The developing parasitophorous vacuole (*pv*) is devoid of intramembrane particles (*Pe* zoite plasmalemma, *H* host cell ► [cytoplasm](#). *bar* = 1 μ m; Dubremetz, Ferreira, and Torpier, original)

The contribution of the apical secretory organelles to invasion is essential. They undergo sequential exocytosis during the process. Micronemes release proteins involved in motility recognition adhesion, at an early stage of interaction. Rhoptries then contribute components of the moving junction (RON proteins, exclusively located in the neck of the organelle) followed by proteins (and lipids) which are integrated into the parasitophorous vacuole membrane (ROP proteins, derived from the posterior part of the organelle). They contribute enzymes such as proteases or phospholipases that can modify the host cell plasmalemma and facilitate vacuole formation (e.g., the cleavage of the erythrocyte protein band 3 by a serine protease of *Plasmodium* is believed to lead to disorganization

of the spectrin network of the red blood cell as a prerequisite to red cell invasion). In addition, some rhoptry proteins are released in the host cell and at least two of them in *T. gondii* are targeted to the host nucleus where they modulate the host cell transcription. Dense granules are exocytosed into the vacuole after invasion and their role is not well understood, yet they are probably involved in rendering the vacuole contents and membrane efficient to sustain parasite metabolic needs. In *P. falciparum*, a ► [dense granule protein \(RESA\)](#) is translocated under the erythrocyte membrane and associates with spectrin.

A peculiar process has been described for the piroplasm ► [Theileria](#): invasion of mononuclear lymphocytes by sporozoites seems to involve a

Apicomplexa, Fig. 8 Schematic drawing of the successive steps of Apicomplexa invasion. (1) A zoite glides on a host-cell surface using microneme proteins exocytosed apically (*curved arrow*); a signal is transduced from the surface (*star, arrow*) to the apex. (2) The signal induces reorientation, apical binding to the host cell, rhoptry neck exocytosis, formation of the moving junction from microneme and rhoptry neck proteins. The bulk of micronemal material is capped behind the moving

junction. (3) Rhoptries are exocytosed while the moving junction glides backward and the parasitophorous vacuole starts expanding. Rhoptry material is integrated in the vacuole membrane. (4) The vacuole keeps expanding, getting most of its lipids from the host cell plasmalemma. The junction reaches the posterior end of the parasite and eventually seals the vacuole. Dense granules are exocytosed in the vacuolar space (After Dubremetz et al. 1998, modified)

zipper mechanism in a receptor-mediated ► **endocytosis** due to specific receptors on the zoite surface. These findings are very unique among Apicomplexa and may represent an exception to the moving junction process. In addition, in this

model, as in the other piroplasm *Babesia* (which invades red cells in a manner very similar to *Plasmodium*), the vacuole membrane is disintegrated after invasion and the parasite develops in the cytoplasm of the host cell.

Apicoplast

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

This term describes an ovoid organelle that is found just prior to the anterior end of the nucleus of motile stages of Apicomplexa (Sporozoa) such

as ► [merozoites](#), sporozoites, tachyzoites, bradyzoites, cystozoites, etc. In early times of electron microscopy, it was described as thick walled vesicle with an unknown function in stages of e.g., ► *Toxoplasma gondii*, *Sarcocystis* species, *Eimeria* species, *Isospora* species, *Plasmodium* species, etc. Today, high-resolution electron microscopy shows that this organelle possesses four membranes, which apparently originate from a penetrated red algal (prokaryotic) organism being “parasitized” by a chloroplast which formerly had also been a separate organism (Fig. 1). Finally, this red algae was engulfed by an autotrophic protist, the progeny of which later developed by coevolution into the parasite species of our days.

Apicoplast, Fig. 1 The diagrammatic representation shows in section (a) an autotrophic protist (yellow, AU), which engulfs an organism, which is supposed to have been a red algae cell (R) with its chloroplast (C, green) (b). Both together (red algae plus its chloroplast) became during evolution the apicoplast (AP) in the infectious stages (merozoites, sporozoites, tachyzoites, bradyzoites, zoites,

and cyst merozoites) of the apicomplexan genera such as *Toxoplasma*, *Sarcocystis*, *Plasmodium*, *Eimeria*, *Isospora*, etc. AP apicoplast (with 4 membranes), AU autotrophic cell, C chloroplast, F flagellum, IN invagination during ingestion of the red algae cell, N nucleus, R former red algae cell

Apicoplast, Fig. 2 TEM of a section through the apical pole of a cystozoite of *T. gondii*. The light blue organelle (right) is the apicoplast

A

The apicoplast is an essential organelle in apicomplexan parasites and apparently provides isoprenoids, fatty acids, and possibly iron-sulfur clusters to the parasitic cell stage. Thus its activity may be stopped by chemical compounds such as doxycycline, fosmidomycine, 15-deoxyspergualin, etc. The division of the apicoplast is coupled to the cell division of the parasite and is commonly seen during the phase, when the nucleus appears u-shaped (with two tips) during nuclear division. Recent findings show that the transport across the periplastid membrane is mediated by an ERAD-derived complex retrofitted for protein import, while the transport across the inner two membranes seems to occur via the so-called Toc/Tic-based system, which is known to occur in plastids of plants. This knowledge opens a broad field of possibilities to kill apicoplast containing parasites by compounds stopping the protein traffic (Fig. 2).

Apicoplast Genomes

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Recent studies offer deeper insights into the genomes of apicomplexan parasites. It was shown that *Leucocytozoon caulleryi* and *Plasmodium falciparum* are rather similar. They contain DNA of 85.1 % AS + T and a unit of 34,779 bp encoding almost the same set of genes including 16 + RNA and 30 protein coding genes. Only one open reading frame (ORF91) is absent in *L. caulleryi*. Both species contain in their apicoplast DNA two sets of a unique inverted repeat (IR) or 5,253 bp and encoding genes specifying one large and one small rRNA subunit and 9 + RNAs but no protein and separated by a unique 13 bp sequence. The phylogeny of the

Apicoplast Genomes, Fig. 1 Phylogeny of the apicoplast genomes. Amino acid sequences specified by the ten selected plastid-encoded genes were concatenated for each species, and the phylogeny was analyzed by the maximum likelihood method with the JTT + F + T model to obtain the dendrogram. *Numbers at nodes* indicate

bootstrap values from 1,000 replicates. The *scale bar* indicates 0.2 substitutions per site. The accession numbers of the nucleotide sequence data, from which the amino acid sequences used in the analysis were deduced, are given in parentheses after the name of each taxon

Apophallus donicus

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Tiny trematode in the intestine of fishing herons.
 The first intermediate hosts are the prosobranchial
 snails (e.g., *Litoglyphus naticoides*), while young
 cyprinid fish act as second intermediate hosts. The
 penetrated cercariae are transformed there inside
 the skin to dark metacercariae of 1.5 mm in diam-
 eter and introduce the so-called “black-dots-
 disease” of carps.

Apophallus muehlingi

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name

Greek: *apo* = away, not present; *phallus* =
 penis; Muehling: name of its discoverer.

This parasite belongs to the digenean trema-
 todes (family Heterophyidae) and is related to
 ► [Heterophyes](#) species, which also involve fish
 as intermediate hosts. The life cycle was described
 by Odening (1970) (Fig. 1).

Apoptosis

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Metazoa are known to possess a sophisticated
 machinery of programmed cell death (PCD),
 which limits the life span of cells and prohibits
 cell exaggeration leading to tumors. Recently
 PCD has also been found in parasitic protozoans,
 e.g., in trypanosomes, malaria parasites,
 leishmanian species, trichomonads. As apoptotic
 markers had been described: chromatin conden-
 sation, DNA fragmentation, externalization of

Apophallus muehlingi, Fig. 1 Life cycle of the digenean *Apophallus muehlingi* that parasitizes in the intestine of several fish-eating animals (a) according to Odening (1970); this species occurs especially in the region of the Eastern Sea and Black Sea. 1 Adult worm (about 0.8 mm long). 2 Operculated and fully embryonated eggs ($34 \times 28 \mu\text{m}$) are set free with the feces of the hosts. The ► **miracidium** does not leave the egg until it is ingested by fresh water or brackish water snails (b), *Lithoglyphus naticoides*. 3–6 Inside the snails reproduction occurs via $650 \times 140 \mu\text{m}$ -sized ► **rediae** (3, 4), within which tailed

► **cercariae** (5) with eyespots are formed. These stages measure including tails up to $700 \mu\text{m}$, leave the snails and penetrate into cyprinid fish (c), in whose fins they become encysted as metacercariae (6). When such infected fish are eaten by the final hosts, the metacercariae leave the cysts in their intestine and mature to adult worms within 7 days, e.g., in *Larus* seabirds. C cercaria, DR redia with 6–12 cercarial embryos, E eyespot, H head of cercaria, IN intestine, MI miracidium, MR mother redia, OP ► **operculum**, T tail of ► **cercaria**

phosphatidylserine, and caspase-like activities. This way of self-limitation in protozoans is much less complex than in metazoan. It brings the advantage to these parasites, that they do not lose their hosts by killing them, before a small part of the population has been transferred to the next host. Thus the parasite density in a host does not rely exclusively on the host's immune system. Since the apoptosis of protozoans is different from that of metazoans, it might be used as target for new chemotherapeutics.

However, intracellular parasites have also developed methods to survive by maintaining their host cell, if the natural response of the infected cells is leading to the reaction to commit apoptosis and thus to deprive the invader of the opportunity to multiply and to disseminate. Such protection from apoptosis is found, e.g., in cells parasitized, e.g., by ► *Toxoplasma gondii*, ► *Leishmania* spp. or ► *Theileria* stages. The latter even stimulate their host cells (lymphocytes) to constantly repeated divisions like that of tumor cells.

Apoptosis in Schistosomes

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *apo* = away; *ptosis* = deletion.

Recent studies showed that there exist components for an intrinsic, B-cell lymphoma-2 (Bcl-2)-regulated apoptotic cell death pathway, which seems similar to that of humans.

Aporina delafondi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Tapeworm belonging to the family Anoplocephalidae (tapeworms of horses, cattle, birds, rodents, and related groups). *A. delafondi* is a synonym for *Killgrewia delafondi*, which was described in Europe, Asia, Africa, and North America. *A. delafondi* occurs in the intestine of doves, reaches a length of up to 23 cm and a width of 0.5 cm. Intermediate hosts are oribatid mites.

Aporocotyle

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *a* = without; *poros* = opening; *kotyle* = sucker; the name describes that these worms have no suckers.

Morphology/Life Cycle

Genus of digenetic trematodes, which reach a length of about 5 mm and parasitize inside blood vessels of gills and other organs of salt and freshwater fish. Their surface contains numerous spines, which allow attachment at their parasitizing sites. The eggs of this genus appear spindle

like, measure $125 \times 35 \mu\text{m}$, and contain a so-called miracidium larva, which (when hatched in water) penetrates into, e.g., *Lymnaea* snails or into polychaetes, which thus become intermediate hosts. Inside these hosts finally sporocysts are developed producing infectious cercariae, which look similar to those of *Schistosoma* species, since their tail is furcated. These cercariae enter the skin of fish. The adults do not possess oral and ventral suckers in contrast to other digenetic genera. For morphology see ► [Sanguinicola inermis](#).

Symptoms of Disease

Infected fish show reduced motion, possess pale gills, have breathing problems, suffer from loss of weight, blockage of blood vessels, and show considerable swellings of the body due to blockages. Death is common in infections with numerous worms.

Diagnosis

Microscopical demonstration of typical eggs in biopsies of gills.

Prevention

No introduction of snails in water with farmed fish, and quarantine for 4–6 weeks of new fish before introducing them into ponds with healthy fishes.

Treatment

Isolation of infected fish and treatment inside separate water containing praziquantel (e.g., Droncit®) solution for farms or praziquantel (Tremazol®) for aquaria/ornamental fish (Fa. Sera, Heinsberg, Germany).

General Information

Arboviruses (arthropod-borne) is a collective name for those viruses which (1) replicate in

certain arthropods and (2) in certain vertebrates and which are (3) transmitted by bloodsucking arthropods between their vertebrate hosts with the saliva during their blood meals. The biological (=cyclic) transmission with replication of the virus in the arthropod is a crucial criterion. A virus adhering to the mouthparts of a blood-sucking arthropod and transmitted mechanically without prior replication in the salivary glands is not an arbovirus. Thus, arbovirus is only an ecological and biological term without any phylogenetic relevance (Fig. 1).

System

Arboviruses are to be found in different virus families: among double-stranded DNA viruses (*Asfarviridae*, ► [African swine fever virus](#)), among double-stranded RNA viruses (► *Reoviridae*, *Orbivirus*, *Coltivirus*, *Seadornavirus*), among negative-sense single-stranded RNA viruses (► *Rhabdoviridae*, *Vesiculovirus*, *Ephemerovirus*; ► *Orthomyxoviridae*, *Thogoto-like viruses*; ► *Bunyaviridae*, *Bunyavirus*, *Nairovirus*, *Phlebovirus*), and among positive-sense single-stranded RNA viruses (► *Flaviviridae*, ► *Flavivirus*; ► *Togaviridae*, *Alphavirus*). Altogether about 600 viruses have been assigned to the arboviruses, some of them were withdrawn later, but in most of them, the abovementioned criteria could be proved, and in some (which have been isolated either from arthropods or from vertebrates only), the arbovirus nature has been concluded from close antigenic relationships to other confirmed arboviruses. Most arboviruses are to be found among the ► *Reoviridae* (about 150 species), *Bunyaviridae* (about 200 species), ► *Flaviviridae* (about 60 species), and ► *Togaviridae* (about 30 species). Among the other families (apart from the family *Asfarviridae*), arboviruses are more or less exceptional. Table 1 gives an overview of the genera of those virus families (also comprising arboviruses).

Some of the viruses called “species” have turned out or will turn out to represent only slightly different strains of other “species”; on

Arboviruses,
Fig. 1 Arbovirus cycles

the other hand, there is no doubt that a large number of arboviruses still remain to be detected. Moreover, one can hardly doubt that – besides many arboviruses without any medical significance – viruses causing (known or unknown) diseases in man and/or animals will also be discovered. It is difficult to estimate how many arboviruses may exist – possibly several thousands. Thus arboviruses will continue to form an important challenge to virologists as well as to parasitologists. The tables Arbovirus (► *ASF viruses*, ► *Asfarviridae*, ► *Bunyaviridae*, ► *Flavivirus*, ► *Orthomyxoviridae*, ► *Reoviridae*, ► *Rhabdoviridae*, ► *Togaviridae*) list selected species of arboviruses with indication of hosts, distribution, and diseases in man and animals. These tables include all arboviruses causing diseases of major significance and/or prevalence and representatives of all families. Most remaining species are poorly known. Some of them apparently cause febrile illness in man (and animals), but many have so far (under natural conditions) not yet been correlated to any symptoms in man or animals (which does not necessarily mean that they are strictly apathogenic, of course).

It should be noted that the concept of species, genera, and families in virology is quite different

from that in other biological disciplines and that a real phylogenetic system of viruses does not and will not exist for principal reasons. Viruses derive from living organisms; thus similar viruses may have quite different and independent origins, although evolution, following the well-known factors of mutation, selection, isolation, etc., does occur to a certain extent within certain taxonomic entities, of course, so that monophyla do also exist at various levels among viruses. Most virus families and at least many virus genera are, however, not monophyla but assemblies of members with a high degree of (genomic) similarities and, in many cases, of similar but independent origins. It has been suggested that at least most arboviruses derive from their arthropod hosts. This assumption is supported by the fact that arboviruses usually do not cause disease or life-threatening damage in their arthropod hosts (exceptions exist, particularly among *Togaviridae*) but often cause more or less serious harm in their vertebrate hosts.

Important Families

The important families of arboviruses are shown in Table 1.

Arboviruses, Table 1 Virus families containing arboviruses

Family	Characterization	Genera representing arboviruses	Main arthropod hosts	Genera other than arboviruses (hosts in brackets)
Asfarviridae	ds-DNA viruses, spherical, with envelope, 175-215 nm	Asfivirus	Ceratopogonidae	
Reoviridae	ds-RNA viruses, icosahedral, without envelope, 60-80 nm	Orbivirus	Ceratopogonidae Phlebotominae Culicidae Ixodidae	Orthoreovirus (vertebrates) Rotavirus (vertebrates) Aquareovirus (vertebrates) Cypovirus (invertebrates) Phytoreovirus (plants) Fijivirus (plants) Oryzavirus (plants) Idnoreovirus (invertebrates) Mycoreovirus (fungi)
		Coltivirus	Ixodidae	
		Seadornavirus	Culicidae	
Rhabdoviridae	Negative-sense, nonsegmented, ss-RNA viruses, rod-shaped, with envelope, 100-430×45-100 nm	Vesiculovirus	Culicidae Phlebotominae	Lyssavirus (vertebrates) Cytorhabdovirus (plants) Nucleorhabdovirus (plants)
		Ephemerovirus	Culicidae Phlebotominae	
Orthomyxoviridae	Negative-sense, segmented, ss-RNA, spherical or filamentous, with envelope, 80-120 nm	Thogotovirus	Ixodidae	Influenza virus A (vertebrates) Influenza virus B (vertebrates) Influenza virus C (vertebrates) Isavirus (vertebrates)
Bunyaviridae	Negative-sense, segmented, ss-RNA, spherical, with envelope, 80-120 nm	Orthobunyavirus	Culicidae Ixodidae	Hantavirus (vertebrates) Tospovirus (plants)
		Nairovirus	Ixodidae Argasidae	
		Phlebovirus	Phlebotominae Culicidae Ixodidae	
Flaviviridae	Positive sense nonsegmented ss-RNA, spherical, with envelope, 40-50 nm	Flavivirus	Ixodidae Culicidae	Pestivirus (vertebrates) Hepacivirus (vertebrates)
Togaviridae	Positive sense nonsegmented ss-RNA, spherical, with envelope, 70 nm	Alphavirus	Culicidae	Rubivirus (vertebrates)

Distribution

Arboviruses occur in all continents, even in high latitudes where ► **mosquitoes** may develop large populations. Moreover, seabirds flying far into the north may act as hosts of tick-borne viruses. It is, however, striking that the number of arboviruses

endemic to a certain geographic region increases toward the equator and the subtropical and particularly tropical regions harbor by far the largest number of arboviruses.

In Europe more than 60 arboviruses have been isolated; among these, there are also 6 phleboviruses which are transmitted by sand

flies; they cause papataci fevers or meningitis which occurs in Southern Europe. Even on a Europe-wide scale, the ► [tick-borne encephalitis virus](#) remains the most important arbovirus, but a few others may also lead to diseases of the central nervous system.

Central Europe harbors (at least during certain periods in certain years) 11 arboviruses. Of these 6 are tick-borne: Tribec, Lipovnik, Eyach, Uukuniemi, Bhanja, and tick-borne encephalitis (► [TBE](#)) viruses; all of them are transmitted by ixodid ► [ticks](#), mainly *Ixodes ricinus*. Four viruses are transmitted by mosquitoes: Calovo, Tahyna, Lednice, and West Nile. Calovo is transmitted by Anophelinae, the others by Culicinae. Tribec, Lipovnik, Eyach, Uukuniemi, TBE, Calovo, Tahyna, and (at least partially) Lednice are probably endemic to Central Europe and also hibernate in this part of Europe. Some arboviruses (e.g., Usutu virus) are most probably more or less regularly introduced by migrating birds to Central Europe and may get established for longer periods. Although at least Tahyna and Calovo viruses are endemic (in the sense of occurring in the area throughout the year), it has to be questioned whether Central Europe harbors autochthonous mosquito-borne viruses in the strict biogeographic sense. Of these 11 viruses, 9 may cause diseases in man, the most important of them being tick-borne encephalitis virus which claims many severe cases every year, sometimes sporadically even deaths. (Before the development of a vaccine and the broad application in the human population in some parts (particularly Austria), the importance of TBE in Central Europe was much higher.) The other viruses cause febrile illnesses of various clinical symptoms (Tables ► [Bunyaviridae](#), ► [Flavivirus](#), ► [Reoviridae](#), and ► [Togaviridae](#)).

Due to the complexity of the synecological systems in which arboviruses circulate (see below), preconditions for the maintenance of the virus cycle are usually fulfilled in limited areas only. These areas are called foci to which the viruses are endemic. (The terms “endemic” and “endemisms” have different meanings in biology and medicine. In biology “endemic” means “restricted to a certain biotope or region, mountain

range, island, etc.” In medicine “endemic” is more or less a synonym of “autochthonous.”) Thus, amplification of a focus is usually difficult. Formation of new foci requires suitable ecological conditions. New and dispersed foci may be established by introduction of virus into a suitable biocoenosis by migrating viremic birds or by larger mammals; in particular man may also act as an amplifier host. ► [Dengue](#) and ► [yellow fever](#) are impressive examples of how the migrating species *Homo sapiens* has established numerous new foci of these arbovirus infections in many tropical and subtropical parts of the world. During the eighteenth and nineteenth centuries, yellow fever virus was introduced to several towns in the south of Europe (Spain, Portugal, Italy, France) and was established for shorter periods. In the twentieth century, dengue I virus was introduced to Greece where it led to a major epidemic in 1928. Bluetongue viruses were introduced and caused heavy epidemics among livestock in Southern and Central Europe. Principally, this anthropogenic dispersal of arbovirus infections plays an important role in all arbovirus cycles in which man is the main vertebrate host (see below Fig. 2).

Vectors

The following arthropod families comprise vectors of arboviruses: ► [Ixodidae](#) (hard ► [ticks](#)), ► [Argasidae](#) (soft ticks), Culicidae/Culicinae, ► [Culicidae](#)/Anophelinae (► [mosquitoes](#)), Psychodidae/Phlebotominae (► [sand flies](#)), and ► [Ceratopogonidae](#) (gnats). Moreover, arboviruses have been isolated from some other arthropod families (► [mites](#), ► [bugs](#), ► [fleas](#), ► [blackflies](#), horseflies); it is, however, not clear whether (some of) these may (additionally) act as (natural) hosts and biological vectors.

Life Cycle

Figure 1 shows the basic structure of an arbovirus cycle. Principally two ways can be differentiated: usually the virus is transmitted by bloodsucking

Arboviruses,

Fig. 2 Arbovirus transmission cycle involving humans as natural hosts (e.g., urban transmission cycle of yellow fever)

arthropods (the vector and arthropod host) to a vertebrate in which it leads to viremia. During this period, which usually lasts only a few days, the virus may be taken up by another bloodsucking arthropod. The vertebrate may or may not become ill shortly before, during, or (particularly) after the viremia. Also, man may be integrated into this form of an arbovirus cycle and may develop disease. In several arbovirus cycles, man is even the only vertebrate host maintaining the virus cycle (e.g., dengue, urban yellow fever, chikungunya); in others, man is a dead end of the virus cycle regardless of whether he/she may develop disease or not. Besides this typical form of an arbovirus cycle, there is another one in which the virus may “remain” in its

arthropod host being transmitted vertically – transovarially – to the next generation and then transstadially throughout the larval (and pupal) stages to the adults. Moreover, a sexual (“venereal”) transmission from male to female and vice versa during copulation has also been found in some arboviruses and may occur more often. ► [Transovarial transmission](#) has been established only in a comparatively small number of arboviruses; one may, however, assume that it will principally occur in most (if not all) arboviruses, regardless of whether they are transmitted by ticks, mosquitoes, ► [sand flies](#), or gnats.

An unusual mode of infection has been described in ticks: uninfected ticks feeding

simultaneously with infected ticks on the same host may become infected, despite the absence of a true viremia of the host, by uptake of virus released by the infected ticks, most probably after replication in certain cells of the skin. This mechanism, which is not yet fully understood, might possibly be of greater significance in arboviruses.

Virus ingested during a blood meal first infects epithelial cells lining the midgut; subsequently it is released into the hematocele from where the salivary glands as well as the ovaries can be infected. The susceptibility of the midgut epithelium is the primary determinant for the vector competence of an arthropod. Infection of the salivary glands may take place after secondary amplification in other cells (tissues) or without secondary amplification. The period between the ingestion of virus during a blood meal and the salivary secretion is called extrinsic ► [incubation period](#) (EIP). This interval must not exceed the lifespan of an arthropod acting as a potential vector. In some alphavirus species, the tissue of the midgut is damaged so heavily by the infection that it becomes “perforated,” which enables the virus to enter the hematocele and thus to rapidly infect the salivary glands. This leads to an unusually short extrinsic incubation period.

Temperature is of great influence on the length of the EIP, which usually lasts a few days; increased temperature may lead to a shortening of EIP and/or to an increase of viral replication and in this way to an increase in transmission rates. Coinfections with other pathogens may also have an influence, e.g., microfilariae penetrating the midgut epithelium cause lesions which facilitate the virus transfer to the hematocele. Virus transfer from a mosquito to the vertebrate mainly occurs during probing of the host tissues with the mouthparts in order to find a small vessel. Therefore the first replication takes place in extravascular tissues. In viruses transmitted by ticks, which are ► [pool feeders](#), there is a comparable situation. Other factors influencing the capacity of a given arthropod species for the virus cycle are virus amount in salivary glands, number of generations, population densities and population

dynamics, frequency and duration of blood meal, horizontal and vertical distribution, ► [circadian rhythms](#), and host spectrum. From all these factors, the number of individuals capable of transmission in a given biocoenosis results as a key parameter.

Vertebrate hosts of arboviruses comprise numerous mammals on the one hand and birds on the other hand; moreover in a few cases, reptiles or amphibians are (or may be) of importance. The suitability of a given vertebrate species to act as a host significant to the maintenance of the cycle depends on several factors, the most important being virus concentrations reached during viremia and length of viremia as a crucial prerequisite to successfully infect a sufficiently high number of vectors. Other parameters are population density, population dynamics, reproduction rates and life expectation, degree of (homologous and heterologous) immunization in a population, horizontal and vertical activity, circadian rhythm, and spectrum of bloodsucking parasites; from these parameters, the number of susceptible and finally the number of viremic vertebrate hosts result.

Taking all these factors into consideration from the perspective of the arthropods on the one hand and of the vertebrates on the other hand, a very complex and rather vulnerable synecological system results.

In arboviruses occurring in temperate zones, an important ecological problem in the virus cycle results from winter and thus ► [hibernation](#). This can be overcome by several mechanisms: ► [vertical transmission](#) in the arthropod host, survival in hibernating (larval or adult) stages of arthropods, ► [chronic infection](#) in vertebrate hosts with persisting or recrudescing viremia (e.g., in heterothermic mammals like bats and hedgehogs), or regular introduction by migrating birds (with a prolonged viremia) from tropical regions. Hibernation of tick-borne viruses is usually easily achieved by persistence of the virus in the larvae or nymphs and by ► [transstadial transmission](#). In some mosquito-borne viruses, overwintering is also possible in adult mosquitoes (e.g., *Anopheles*

Arboviruses, Fig. 3 Transmission cycle of an arbovirus (tick-borne encephalitis virus) with humans as dead-end hosts. 1 natural transmission cycle between rodents and

ticks, 2 natural transmission from vector (ticks) to humans, 3 unusual transmission from one dead-end host (goat) to humans by milk

spp., *Culiseta* spp., *Culex* spp. hibernating as adults).

Although vertical, transovarial (and sexual) transmission are biologically remarkable phenomena and important mechanisms, it seems unlikely that maintenance of virus in a certain biocoenosis can be achieved by such modes without regular participation of mammals in the virus circulation.

Under certain circumstances, an arbovirus can also be transmitted from one vertebrate to another. A natural way is the ► [galactogenic transmission](#) during lactation to the progeny or (in case of animals whose milk is used) to man (Fig. 3). In

tick-borne encephalitis, smaller outbreaks in the human population due to consumption of raw, infective milk have been described. Virus in the milk is found only during the viremic stage of the lactating animal.

Contact with injured (living or killed) animals can also lead to infection as it has been known from arboviruses with vertebrate hosts which are hunted or slaughtered. This is of particular importance in the transmission of Rift Valley fever, Crimean-Congo hemorrhagic fever, or Alkhurma hemorrhagic fever to man.

Finally there are also a few viruses which have never been isolated from an arthropod and which

are apparently transmitted between their vertebrate hosts by close contact only (e.g., Modoc, Rio Bravo). These viruses are not arboviruses by definition; they have, however, been included due to their close antigenic relationship to other viruses which present all characters of a real arbovirus.

From the viewpoint of host capacity for arbovirus circulation, vertebrates can be assigned to three groups: (1) species which are not susceptible (natural resistance, e.g., due to the lack of receptors) at all and in which, therefore, no virus replication will take place; (2) species which are susceptible but will develop only a low (and/or short) viremia which is not sufficient for a successful infection of arthropod dead-end hosts (these species are therefore of no significance for the maintenance of the virus cycle); and (3) species which are susceptible and will develop a viremia sufficiently high and long to infect arthropods (natural vertebrate hosts). These are the species maintaining the virus cycle. Apart from the intensity and duration of viremia, species of groups (2) and (3) may, but need not necessarily, develop a disease. Usually those vertebrates which are essential for the maintenance of the cycle will not develop (a life-threatening) disease; in many cases they do not even show any symptoms. This seems to be in good agreement with general considerations on parasites; one must, however, take into consideration that a vertebrate infected with a virus will develop immunity which prevents reinfection. Thus a vertebrate host can contribute to the virus cycle directly during its viremic stage only for a very short period. After that (apart from very rare ► [chronic infections](#) with persisting or relapsing viremia), the vertebrate will not be a source of infection. Nevertheless, it may contribute indirectly to the virus circulation by acting as a host for arthropods which maintain the circulation (e.g., ticks will reach higher populations if hosts are abundant). Therefore vertebrate species developing severe disease with a high mortality may also act as maintaining hosts, particularly if they have high population densities with a sufficient percentage of nonimmune individuals. Dengue and yellow fever are good examples; in urban areas with circulation between Culicidae (*Aedes*

aegypti) on the one hand and man on the other hand, man will develop serious disease. In many cases those vertebrate species which suffer from life-threatening arbovirus infections (e.g., horses infected with EEE or WEE) do not develop sufficiently high viremia to be of any importance for the virus cycle.

Syndromes

Out of the 600 arboviruses described so far, about 150 have proved to be pathogenic for man. In some infections, only antibodies, but no symptoms, were found thus at least indicating that man is susceptible. The syndromes caused by arbovirus infections can be roughly divided into (1) febrile illnesses, usually with headache and rash, with or without arthralgia and polyarthrits (dengue, West Nile, chikungunya, Mayaro, Ockelbo, o'nyong-nyong, Ross River, Semliki, Sindbis, and many others), and sometimes, however, also with neurological symptoms (e.g., in recent outbreaks of West Nile infections); (2) hemorrhagic fever (► [Crimean-Congo hemorrhagic fever](#), ► [Omsk hemorrhagic fever](#), ► [Kyasanur forest disease](#), dengue, yellow fever, Rift Valley fever, Alkhurma fever, Garissa fever); and (3) neurological disorders with meningitis and ► [encephalitis](#) (Kyasanur forest disease, Powassan, tick-borne encephalitis, Eastern equine encephalitis, Venezuelan equine encephalitis, Western equine encephalitis, and others).

Arbovirus infections have a tremendous impact on human health throughout the world. Every year millions of people become infected by arboviruses, many hundreds of thousands of whom develop diseases. Every year smaller or larger epidemics – e.g., due to dengue viruses, yellow fever virus, chikungunya virus, Japanese encephalitis virus, Rift Valley virus, etc., with a varying number of deaths – are reported. Also the economic loss in livestock due to arbovirus infections is serious. Several arbovirus infections have been of considerable influence on human history. Yellow fever (which was most likely introduced to America during the dark era of transports of slaves from Africa) led to a defeat of the French army on

the Caribbees at the beginning of the nineteenth century so that Napoleon was forced to sell Louisiana to the USA, thus putting an end to French colonial strategies and influence in North America. Later in the 1880s, yellow fever thwarted the construction of the Panama Canal and led to a financial disaster and condemnation and the sentencing of the famous French engineers A. G. Eiffel and F. Lesseps. Only at the beginning of the twentieth century, after it had generally been accepted that yellow fever is transmitted by mosquitoes, mainly *Aedes aegypti*, and that mosquito control is crucial for fighting against yellow fever, the Panama Canal could be built.

Therapy

There are no specific drugs for treatment of any arbovirus infection; only symptomatic treatment is possible.

Vaccines

There are only three arboviruses against which vaccines are available and in general use: tick-borne encephalitis virus (inactivated virus propagated in chicken cells), Japanese encephalitis virus (inactivated virus propagated in mouse CNS or in hamster kidneys or – in China – a living attenuated strain), and yellow fever virus (attenuated strains). In addition, several “noncommercial” vaccines against a few arboviruses have been in use to protect laboratory and veterinary workers (e.g., against Rift Valley fever and Eastern, Western, and Venezuelan equine encephalitis). These are usually inactivated vaccines, but also living vaccines (e.g., VEE) are in use. Moreover, a vaccine (attenuated strain) against dengue has been developed and is now tested in field trials.

Archigetes Species

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *archi* = very old.

Archigetes species (Fig. 1) belong to the monozoic tapeworm order **Caryophyllidea**.

Archigetes Species, Fig. 1 (a, b) Life cycles of *Archigetes iowensis* (a) and *A. sieboldi* (b) according to Machiewicz and others. 1 The monoecious sexually mature stages live in the intestine of many fish species (a) or in the body cavity of oligochaetes (= annelids; *Limnodrilus*, *Tubifex*). According to some authors, *A. sieboldi* should also develop fertile stages in fish hosts. 2 Unembryonated eggs enter the water with the feces (a) or after death of the oligochaete (b). 3 Embryonation is completed after about 14–16 days in water of about 18–22 °C, leading to the formation of an ► **oncosphaera** (ON). These eggs are infective for the next host. In *A. sieboldi* the development (1–3) is repeated in another oligochaete (i.e., indirect development). Since the sexually mature stages are proceroids, this development is progenetic. 4–6

In *A. iowensis* an intermediate host is obligatorily involved; this may also occur (according to recent articles) in *A. sieboldi*, if fishes are used as final hosts. When oligochaetes swallow infective eggs, the oncosphere escapes from the egg and penetrates into the body cavity. Each oncosphere develops into a ► **proceroid** larva at this site. Each proceroid forms complete reproductive organs within 60 days (6). When such proceroids are ingested by a final host, the larva loses its ► **cercomer**, becomes adult, and starts production of sperms and ► **oocytes**. After copulation eggs are passed with the host feces. BO bothrium (acetabular sucker), E egg cell, HO hooks of oncosphaera, N nucleus, ON oncosphaera, OP operculum, OV ovary, TA tail, TE testis, UE uterus (gravid) filled with eggs, UT uterus, VC vitellary cell, VI vitellary glands (► **Vitellarium**)

Adults (0.5–3 cm long) are described worldwide. They live as intestinal parasites in fresh water fishes, but larvae are found in tubificid worms. Their body lacks internal or external segmentation and includes just one set of female and male sexual organs unlike all other Eucestoda. Worldwide about 41 genera of the Caryophyllidea are described with a total of around 150 families.

This is a Golgi protein, which is involved in trafficking (e.g., expressed in bloodstream stages of ► *Trypanosoma cruzi*).

Argas Species, Leather or Soft Ticks

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

General Information

1. **Name:** Griech: *argos* = bright; Latin: *reflexus* = bended, curved; *polonicus* = from Poland; *persicus* = from Persia (today Iran).
2. **Geographic distribution/epidemiology:** Worldwide, depending on the species; in some houses or chicken stables, crowding of tick stages often occurs. In the absence of birds, *Argas* ticks also attack humans.
3. **Morphology/life cycle:** The developmental stages of the *Argas* species have a dorsoventrally flattened body, which looks ovoid when seen from the dorsal side (Figs. 1 and 2). When looking at the ventral side of *Argas* nymphs and adults, 8 legs, mouthparts, cheliceres, hypostome, pedipalps, centrally situated genital opening, and the anus can be observed (Fig. 3). Larvae have only six legs and their sucking apparatus (capitulum) surpasses the anterior body end. Males look very similar to females but are somewhat shorter in all species. Nymphs measure 3.5–6.5 mm in length, while males may reach 7.5 mm and females up to 1.2 cm. All developmental stages (Fig. 4)

Argas Species, Leather or Soft Ticks, Fig. 1 Light micrograph of four *Argas* ticks: two are laying on their back

Argas Species, Leather or Soft Ticks, Fig. 2 Diagrammatic representation of the backside aspect of an *Argas* tick

suck blood. While larvae remain attached for 5–10 days at the host's skin, nymphs and adults suck (at night) only for about ½ h in mean ingesting up to 0.3 ml blood. This may lead to a considerable loss of blood, in case numerous specimens attack a single host (as it is mostly the rule). The whole development from egg to adult ♀ or ♂ normally takes 3–6 months but may be stretched up to 2–3 years in the absence of hosts. This shows that these

Argas Species, Leather or Soft Ticks, Fig. 3 Scanning electron micrograph of the ventral side of an *Argas* tick

ticks are able to starve for a rather long time (e.g., when staying in an empty chicken stable, in an empty holiday house of a family, or in an empty bird nest). *Argas* species are not host specific and attack practically all warm-blooded hosts if available. The main host range, however, consists of birds (pigeons, chicken, ducks, goose, wild birds). Copulation occurs far from a host just after a blood meal. The females depone at hidden places 4–6 times a bunch of about 80 eggs (Fig. 4), which give rise to larvae within 2–8 weeks depending from the temperature. Thus it takes time until a chicken stable or a human dwelling is overcrowded with *Argas* stages. The following species are described:

- (a) *Argas reflexus* is named pigeon tick, but it attacks indoor and also other house birds in European regions until 55° N.
- (b) *Argas persicus* (chicken tick, occurs in warm countries).
- (c) *Argas polonicus* (occurs in some regions of Eastern Europe).

Argas Species, Leather or Soft Ticks, Fig. 4 Diagrammatic representation of the life cycle stages of *Argas* species and their feeding periods. Note that in general

only a single larva occurs and is followed by four nymphs and finally by a male or female tick. Each developmental stage emerges from the proceeding one by a complete molt

4. **Symptoms of tick infestation:** Adult hosts show weakness and anemia due to loss of blood. Juvenile pigeons may even die. Birds may also show loss of feathers. In case of absence of birds, these ticks also attack humans, where the biting sites become inflamed and introduce severe itching. Just after blood sucking, skin swellings (bumps) occur, which reach diameters of 1 cm in humans, and appear as reddish blue hemorrhages.
5. **Diagnosis:** Search for attached tick larvae at the skin of birds and for nymphs and adults in hiding places inside stables or in dwellings.
6. **Infestation:** *Argas* larvae are nightly active and suck blood several times in a month. Nymphs and adults are only temporary ectoparasites and digest their blood meal apart from their hosts.
7. **Prophylaxis:** Stables or human dwelling should be kept free from invading ticks. In stables possible hiding places should be sprayed with acaricides. To protect human dwellings, it is recommended to keep away pigeons from balconies and/or windowsills. During the construction phase of houses, pigeons should be driven away until the house is closed by a roof, window glasses, and doors.
8. **Control measures:** Use of contact acaricides to kill hidden *Argas* stages in wall grooves, bird nests, floor hollows, etc. Nonpoisonous neem-seed extracts (MiteStop[®], Fa. Alpha-Biocare, Düsseldorf) suffocate hidden specimens or attached larvae.

Argasidae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Leather ticks; Soft ticks

Classification

Family of ► [ticks](#) (genera *Argas*, ► *Ornithodoros*). ► [Acarina](#).

Characteristics

Capitulum not visible from dorsal (except for larvae), the openings of the respiratory system (stigmata) are situated laterally between the pairs of legs III and IV.

Argonaute Protein Family

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: heroic sailors on the search for the golden fleece.

These proteins are subdivided into different clades. Platyhelminths evolved the group 4 of the Ago called subfamily of such proteins.

Argulol[®]

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Concentrated treating compound to clear parasitic infections of fish living in aquaria or ponds. Produced by Alpha-Biocare GmbH (Düsseldorf, Germany, www.alphabiocare.de) and sold by Fa. Sera, Heinsberg, Germany (www.sera.de). The product includes 10 mg emamectin benzoate per ml, macrogol 300 propylene carbonate, and denatonium benzoate. The following ectoparasites are killed: carp lice (e.g., ► *Argulus* species), gill crustaceans (e.g., ► *Ergasilus* species and isopods), and anchor worms (e.g., *Lernaea* species). The product is diluted in the water of aquaria and/or ponds. **Doses:** 2 ml Argulol[®] per 100 l water for 3 h in aquaria or 5 ml Argulol[®] per 1,000 l water in ponds (see declaration sheet).

Argulus

Genus of the class ► *Branchiura* of the crustaceans; the specimens reach 6–22 mm in length

and parasitize (they suck blood and lick digested epidermis) fresh- and saltwater fish. The females of the species *A. foliaceus* (carp; Fig. 1), and *A. coregoni* (salmon) may swim and deposit their eggs at the bottom of the habitat. As opposed to ► *nauplius* larvae, young adults hatch from the eggs. During sucking *Argulus* species may transmit a broad spectrum of viruses and bacteria (Fig. 2).

An analogue of purine, stops the hypoxanthine transport in chicken coccidians, ► [Coccidiocidal Drugs](#).

Arrenurus Species

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

This genus of water mites contains several species, which parasitize temporarily on the surface of fish. The larvae possess as all mites only six legs (Fig. 1), while nymphs and adults have eight legs. Since all stages (Fig. 2) suck body fluids, they may transmit mechanically agents of disease

Arrenurus Species, Fig. 1 Diagrammatic representation of the ventral side of a larva of the mite *Arrenurus* sp.

Arrenurus Species, Fig. 2 Micrograph of an *Arrenurus* mite on a fish skin

into wounds, which they produce by their mouthparts.

Arrested Larvae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Delayed development (► [Hypobiosis](#)). In autumn trichostrongylid larvae stop further development inside the tissues of their hosts. In spring these arrested larvae resume their development to become adults.

Arsanilic Acid

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This compound, which is also known as aminophenyl arsenic acid and aminophenyl

arsonic acid, is an organoarsenic compound with the molecular formula $C_6H_8AsNO_3$. A special formulation was used in former times under the name ► [Atoxyl](#) against the agents of African sleeping sickness (► [Trypanosoma](#) species). Another formulation – developed by ► [Paul Ehrlich](#) and produced as Salvarsan® by Farbwerke Hoechst – was the drug of choice against the venereal disease syphilis for nearly 40 years. This worldwide success started the century of chemotherapy. For long time, arsanilic acid was added to the food of chicken and piglets, promoting growth and prohibiting dysentery.

Artemether

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This is a methyl ether derivative of ▶ [artemisinin](#), which is used in combination with lumefantrine to treat multidrug resistant strains of *Plasmodium falciparum* malaria. It was first marketed as Riamet® and Coartem® by Novartis (Basel, Switzerland) and later by several generic manufacturers worldwide.

Artemisinin

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This formulation of an antimalarial drug has been originally developed in the year 1972 in the Chinese Institute of Material Medicine at Guangzhou by Mrs. Youyou TU. The basic material was obtained from the salt plant *Artemisia annua* (Sweet wormwood). The artemisinin has already been used in former times in China inside a plant derived tea called Quinhao to treat fevers like those of malaria but also to treat haemorrhoids. In chemical terms, artemisinin is defined as a sesquiterpene lactone (C₁₅H₂₂O₅) from which several derivatives have been isolated: artemether, artesunate, arteether, and artelinate. While artemisinin, artemether, and arteether are water soluble, the two other formulations are not. The antimalarial activity is produced as soon as dihydroartemisinin is formed by conversion of artemisinin and the other compounds are transformed into their active plasma metabolites.

Artemisinin acts mainly against the early asexual stages of the human *Plasmodium* species and thus blocks as early as possible the formation of a new generation of parasites. This early activity decreases the life-threatening increase of the blood parasitaemia. Parasite clearance times of infected blood are found to be shorter than after application of ▶ [chloroquine](#). Therefore the symptomatic response is considerably quicker and avoids some fever shocks, e.g., within 48 h 70 % of the treated cases became afebrile and the peripheral smears in cases with infections by *P. vivax*, *P. malariae*, and *P. falciparum* were usually negative in 100 % at a well-tolerable status and without relapses.

Dosis and treatment schemes (especially those of recommended combination therapies) see ▶ [Malaria](#) treatment (Fig. 1).

Artemisinin: Modes of Action

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The modern antimalarial compound artemisinin (Qinghaosu) is claimed to act in the following ways after being activated through cleavage of the intrinsic bond:

- Interference with the heme detoxification pathway
- Induction of the alkylation of the translationally controlled tumor protein (P70S6) and of other proteins
- Inhibition of the sarco/endoplasmic reticulum membrane calcium ATPase
- Inference with *Plasmodium* mitochondrial functions

Artemisinin-Based Combination Therapy (ACT)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

WHO recommended in 2010 and 2012 to use artemisinine (► [qinghaosu](#)) plus a partner drug in order to optimize treatment of malaria. The following combinations were proposed for the first line treatment of uncomplicated cases of *Plasmodium falciparum* ► [malaria](#) in adults and children:

1. Artemether + lumefantrine (AL)
2. Artesunate + amodiaquine (AS + AQ)
3. Artesunate + mefloquine (AS + MQ)
4. Artesunate + sulfadoxine-pyrimethamine (AS + SP)
5. Dihydroartemisinin + piperquine (DHA + PPQ)

Artesunate

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

► [Malariacidal Drugs](#) = agents against protozoal diseases.

Arthropoda

Name

Greek: *arthron* = segment, *pus, podos* = foot.

Classification

Phylum of ► [Metazoa](#).

General Information

The metameric arthropods are named with respect to their segmented legs (► [Acarina](#), ► [Mites](#)) which probably derive from locomotory appendages similar to the parapodia of recent polychaetes. The chitin-protein exoskeleton is common to all groups of arthropods, is secreted by chitogenous cells of the epidermis (hypodermis) beneath it, and not only covers the external surface, but also passes through the mouth into the anterior part of the intestine (Stomodaeum) and through the anus into the rectal part of the alimentary system (Proctodaeum). The exoskeleton in the form of chitinous plates (sclerites) covers the metamerically arranged segments of the animal. The single plates are connected by fine membranous elements, thus allowing movements and body flexing by means of the strong inner muscular systems and the hydrostatic pressure of the body fluid. The chitinous cover would hinder growth of the arthropods;

thus, it is cast off periodically and a new larger exoskeleton is formed during molt (► [Ecdysis](#)). Most arthropods are monoecious; copulation and internal fertilization are characteristic of the majority of species. Ontogenesis proceeds in all parasitic forms as ► [metamorphosis](#) involving at least one and sometimes several larval (nymphal) stages. The circulatory system is open with a primitive dorsal heart; respiratory systems of various kinds (gills, trachea, lungs, etc.) may occur, just as different forms of the excretory tract (Malpighian tubules, coxal and antennal glands, etc., ► [Insects](#), Fig. 6, ► [Mites](#), Fig. 7).

Arthropods have traditionally been divided into two subphyla. Those with antennae have been placed within the subphylum ► [Mandibulata](#), thus named because the first postoral appendages are mandibles. Those that lack antennae and mandibles are commonly placed in the subphylum ► [Amandibulata](#) (others prefer the term ► [Chelicerata](#), thus named because the first postoral appendages become feeding organs called ► [chelicerae](#)).

System

Recent classifications of the arthropods are under discussion (especially the rank of different taxonomic groups). However, the following groups are accepted *in toto*:

Phylum: Arthropoda.

Subphylum: Trilobitomorpha (the fossil trilobites).

Subphylum: ► [Chelicerata](#).

- Class: Merostomata (horseshoe crabs and fossil erypterids).
- Class: Arachnida (including orders Araneae = ► [spiders](#), ► [scorpions](#), ► [Acarina](#) = ► [ticks](#), ► [mites](#), etc.).
- Class: Pycnogonida (= Pantopoda, sea spiders).

Subphylum: Tracheata.

- Class: Chilopoda.
- Class: Progoneata.
- Class: Insecta (Hexapoda).

Subphylum: Diantennata (Branchiata).

- Class: ► [Crustacea](#).

Intestine and Food Uptake

The structure of the intestine and its appendages varies considerably among the various arthropod taxa, depending on their different ways of living and feeding. Even when they feed in the same way (e.g., blood-sucking), different (though convergent) structures, methods, and strategies have developed in ► [insects](#), ► [mites](#) and ► [ticks](#).

Arthropodicidal Drugs

Andreas Turberg

Bayer Healthcare AG, Bayer Animal Health GmbH, GDD-AH-PARA-APR, Monheim, Germany

General Information

Much of the increase in animal productivity as well as prevention and treatment of parasitic diseases over the past half century has been due to more efficacious and economical control of arthropods through the use of synthetical chemical compounds.

Chemical control of parasitic arthropods is a critical resource for worldwide food production as well as human or animal health. There is little doubt that it will remain so for the foreseeable future, but it is also important that progress be made to sustain and enhance its contribution. Achieving this progress depends to a great extent on the synthesis of new parasiticides, a field in research-orientated life science companies that is still highly dynamic.

In the livestock- and companion animal field the demand for chemical control measures has grown with increasing animal numbers and the world wide increase in consumption of meat (Fig. 1).

Arthropod attack causes a variety of damaging effects including reduction in feed efficiency, growth rate, milk and wool production. In addition to lower quantities of finished products, their

Arthropodicidal Drugs,

Fig. 1 (a) Development of worldwide production capacities of meat between 1986 and 1997. (♦) Beef and veal; (■) mutton and lamb; (▲) pork; (●) poultry. (b) Standing animal populations between 1987 and 1997

quality is also impaired and parasite infestation contributes to a loss of general condition and an increase in susceptibility to secondary infections or further parasite attack.

While the level of parasite infestation is generally less severe in pets than in livestock species, the main health concern with dogs and cats is the danger of transmission of ► fleas, worms, and tick borne diseases to human beings.

The importance of drugs to control arthropods is reflected by the market development for insecticides, acaricides and endectocides displaying activity against some arthropods, and various helminths (avermectinoid drugs).

Arthropodicidal products currently account for around 14 % the world animal health market, which has a value of about US\$ 17 billion (including feed additives). The performance of arthropodicidal drugs has been notable in recent

years, while others have been static or declining. This sector has continually expanded world wide. An amount of US\$ 1600 Million was spent in 1993 for livestock- and companion animal drugs (insecticides, acaricides and endectocides without environmental health insecticides). In 1998 the corresponding value increased by about 40 % to US\$ 2300 Million. This trend looks yet to continue and it is expected that the market may increase by 12 % until 2002.

In terms of volume the growth rate for livestock arthropodicides is expected to be low. In context, however, with the introduction of new highly innovative drugs against ectoparasitocides of dogs and cats, such as advantage® (imidacloprid), program® (lufenuron), and front-line® (fipronil), a significant expansion is expected in the field of pets.

Resistance

The spectrum of parasite resistance is one of the major problems affecting the usage of arthropodicidal drugs.

In some regions the development of this trait has rendered compounds practically useless. One solution is to put more effort into careful promotion of the proper use and rotation or combination of compound used in parasite control in order to prolong the life cycle of the products on the market.

Another possibility, and probably the best long term strategy is to increase the search for drugs displaying an alternative mode of action not interfering with the resistance mechanisms already developed in relevant arthropod pests. Good examples in the area of pets are again imidacloprid, lufenuron and fipronil which act on the nicotinic acetylcholin receptor, chitinbiosynthesis and γ -aminobutyric acid receptor, respectively.

Improvement of Chemical Product Quality

Particularly in livestock the world trend has now moved firmly away from purely quantitative considerations towards quality of products. Concerns about critical side effects of arthropodicidal compounds which affect the classical targets (acetylcholinesterase: organophosphates, carbamates; sodium channel: DDT, pyrethroids; GABA-aminobutyric acid gated chloride channel: chlorinated hydrocarbons) have led the regulatory agencies to demand additionally information and studies in order to define more clearly product efficacy, safety, residue profile and quality. Accompanied by the increasing levels of funding used for regulatory compliance the improvement and innovation in delivery formulations of existing chemical classes was and will be a preferable method for expanding product ranges. Good examples are the development of easy to apply pyrethroid pour on's and spot on's (application of an arthropodicidal drug along the backbone of an animal, or as a spot on in one

place) which have considerably infringed the share of environmentally less favourable dips and sprays.

Increasing expenditure on development have led to a tendency to exploit drug properties also by combining different compounds in one product, thereby providing a broader range of activity within one treatment. In particular the combination of anthelmintic with arthropodicidal drugs such as levamisole and famphur to "produce" activity against ► [stomach worms](#), ► [lung worms](#), cattle grubs and ► [lice](#) or the combination of insect growth regulators with avermectinoid drugs against intestinal worms and flea larvae are of significant interest in this context (Table 1).

Formulation and Delivery Systems

The ease of delivering an arthropodicidal drug has become almost as important in terms of its consumer acceptance as is its activity against parasites. With the increasing levels of funding needed to develop new drugs, the improvement in formulation of existing drugs is fast becoming an important method to expand product ranges.

The future trend of innovative delivery systems will probably focus on stress reduction and improvement of convenience. Losses in weight gain and growth performance as well as costs for handling of livestock species can almost reach the spending on medication. Therefore systems which extend the delivery time such as tablets, boluses or other controlled release devices, will reduce handling frequency and may open up possibilities for new administration technologies (Table 2).

As miniaturisation of electronic devices continues to advance one innovative example might be the development of new bolus types that will release ectoparasiticides, for example insect growth regulators, self- or externally triggered over a long period of time. By eliminating larval development in the pasture and reducing re-infestation such products might play an important role in the strategic management of fly control programs.

Another step forward could be the development of more advanced topical applications such

Arthropodicidal Drugs, Table 1 Combination products with arthropodicidal drugs (According to Hansen and Londershausen)

Example of combination	Main indications	Formulation/ application
Large animal use		
Abamectin/praziquantel	Control of round- and tapeworms as wells as bots in horses	Paste
Amitraz/diazinon	Sheep ectoparasites: flies, keds, lice, ticks	Dip
Cypermethrin/ chlorfenvinphos	Broad tick activity for various host animals, catt lice and flies	Dip/spray
Cypermethrin/rotenone	Longterm protection for sheep against itchmite and lice	Dip
Small animal use		
Lufenuron/milbemycin-oxime	Canine helminths and immature flea stages	Tablet
Permethrin/pyriproxyfen	Larval development stages and adult fleas	Spray
Propoxur/flumethrin	Control of adult fleas and ticks	Collar
Propoxur/methoprene	Environmental control of flea development stages	Spray
Pyrethrin/S-methoprene	Control of fleas and ticks	Spray

Arthropodicidal Drugs, Table 2 Delivery systems of arthropodicidal drugs (According to Turberg and Londershausen)

Method of application	Typical examples of actives or chemical classes used
Major topical formulations	
Collar	Propoxur, amitraz, permethrin, flumethrin, diazinon, deltamethrin,
Dips	Methoprene
Pour-ons	Organophosphates, pyrethroids
Spot-ons	Avermectins, milbemycins, pyrethroids, metaflumizone, amitraz
Sprays/jetting fluids/mist sprays	Fenthion, fipronil, imidacloprid, permethrin amitraz, carbamates, organophosphates, pyrethroids
Other topical formulations	
Aerosols	Organophosphates, pyrethroids, carbamates
Dust bags/back-rubbers/dusts	
eartags/strips	
Foams/shampoos	
Ointments	
Powders	
Washes	
Oral formulations	
Boluses	Methoprene, avermectins, milbemycins
Tablets	
Injection	Avermectins, milbemycins

as pour ons or spot ons involving for example micro-encapsulation technology for livestock and pets.

Wash-off resistance and decreased dermal penetration of adulticidal drugs such as pyrethroids or others will further stimulate the usage of this easy and stress minimising application.

Classes of Chemical Compounds

A wide variety of ectoparasites are relevant for livestock and pets. These resolve into a relatively small number of major problems with a wide variety of products, ingredients and formulation for their control. For information on ► [repellents](#)

Arthropodicidal Drugs, Table 3 Major arthropodicidal chemical classes used in veterinary medicine (According to Turberg and Londershausen)

Chemical class/ examples	Mode of action	Chronology of discovery for veterinary use ^a
Chlorinated hydrocarbons		
DDT	Voltage dependent sodium channel	1943
Cyclodiens, lindane	GABA-gated chloride channel	~1945–1959
Organophosphates	Acetylcholinesterase	~1950–1965
Carbamates	Acetylcholinesterase	~1960–1970
Pyrethroids	Voltage dependent sodium channel	~1970–1985
Amidines	Sites responsive to biogenic amines (octopamine receptors, monoamine oxidases)	~1975–1980
Avermectins/ milbemycins	Glu-gated chloride channel	~1981–1998 ^b
Insect growth regulators		
Cyromazine	Interference with cuticle sclerotization	1979
Benzoylphenylureas	Inhibit cuticle deposition/chitin biosynthesis	~1985–1995
Juvenoids	Mimic juvenile hormone effects	~1988–1996
Arylpyrazole (fipronil)	GABA-gated chloride channel	1994 ^b
Chloronicotinyles (imidacloprid)	Nicotinic acetylcholin receptor	1996 ^b

^aArea of entry date based on the introduction of important actives of the respective chemical class into veterinary market
^bThe discovery and development of further products can be expected due to intensive research efforts in various veterinary companies

and ► [synergists](#) please refer to the respective entries.

Arthropodicidal drugs can be divided into different groups according to their structure and mode of action (Table 3) assuming that similar chemical structure leads to the same basic mode of action. This certainly is a much too simplified view which doesn’t reflect realistically an overall biological activity. Biological effects result from the superimposement of primary mode of action, pharmacokinetic behavior, degradation and excretion driven by the physiochemical parameters of drugs. Chemical compounds may display significantly different properties in this respect, even if they basically belong to the same chemical class.

Organochlorides

Important Compounds

Bromocyclen, chlordan, DDT, lindane (gamma benzene hexachloride), methoxychlor.

General Information

Lindane and several cyclodienes were demonstrated to stimulate the central nervous system by influencing synaptic transmission and causing hyperexcitation. In the 1980s it was shown that these compounds block the (GABA)-influenced Cl[–] current in neurons by binding to the GABA receptor chloride channel. In a set of elegant experiments this theory has been confirmed by showing that target site insensitivity to cyclodienes was associated with a resistance gene (Rdl = resistance to dieldrin) which codes for a GABA receptor subunit in *Drosophila melanogaster*. The responsible point mutation in the membrane spanning region M2 could be identified by cloning of the M2 region with degenerated PCR primers amongst others in a variety of resistant dipteran flies.

Chlorinated hydrocarbons applicated in sprays or dips once were common products for example in the treatment of myiasis and lice infestation in cattle and other species. Nowadays organochlorides such as chlordan, lindane are

no longer approved for veterinary use in many countries, particularly because of their long persistence in the environment. Occasionally compounds like bromocyclen or methoxychlor are used against ► [mange mites](#) biting and sucking lice and flies such as *Melophagus* or *Hippobosca* species.

Organophosphates/Carbamates

Important Compounds

Azamethiphos, bendiocarb, bromopropylate, carbaryl, chlorfenvinphos, chlorpyrifos, coumaphos, cythioate, diazinon, dichlorvos, dicotophos, dioxathion, ethion, famphur, fenchlorphos, fenitrothion, fenthion, heptenophos, iodofenphos, malathion, methomyl, phosmet, phoxim, pirimiphos, promacyl, propetamphos, propoxur, temephos, tetrachlorvinphos, trichlorfon.

General Information

The concept that toxicity to insects and ► [ticks](#) by organophosphates and carbamates results from inhibition of acetylcholinesterase (AChE) was proven to be useful in correlating structure with activity for various compounds from both chemical classes, although some disagreement exists as to the exact mode by which AChE-inhibitors kill ectoparasites.

Organophosphates and carbamates have a wide range of activities against various arthropods, involving blowfly larvae, ► [keds](#), lice, fleas, ► [mites](#) and ticks in companion and live-stock animals. Products with almost any application type have been developed ranging from dips, sprays and pour on's to ear tags and collars. Organophosphates in particular have been popular due to their rapid onset of activity, but in recent years concerns have been raised regarding environmental effects and some adverse reactions. In contrast to organophosphates the carbamylation of AChE by carbaryl and propoxur results in a reversible inhibition of AChE whereas organophosphates inhibit AChE almost irreversibly. The somewhat lower safety level compared to

other insecticides has limited their use on older animals (>3 months) and the development of resistance nowadays restricts their applicability significantly. This problem is especially important in such sectors as the ear tag application.

Pyrethroids and DDT

Important Compounds

Alphamethrin, bioallethrin, cyfluthrin, (beta-) cyfluthrin, cyhalothrin, cypermethrin, deltamethrin, fenvalerate, flucythrinate, flumethrin, (tau-)fluvalinate, permethrin, phenothrin, resmethrin, tetramethrin.

General Information

The symptoms of pyrethroid and DDT poisoning in insects are characterised by different forms of hyper-excitation caused by repetitive discharge of the nervous systems. In patch clamp investigations of single sodium channel currents it has been demonstrated, that under the influence of pyrethroids and DDT individual channels are modified to remain open for an unphysiological long period of time. The symptoms of intoxication differ somewhat between type II and type I pyrethroids based on the presence or absence of a cyano group at the α -position. Taking into account this structural as well as pharmacokinetic differences between various pyrethroids, the basic mechanism of action at the channel and cellular level is the modulation of the gating kinetics of individual sodium channels.

Since natural pyrethroids are not stable enough under atmospheric influences, the use of synthetic pyrethroids in animal health has become an important method to control arthropod pests such as flies and ticks. Various pyrethroids have been developed for animal health indications expressing more or less pronounced broad spectrum activity against ectoparasites. In this context the relation between dosage and occurrence of adverse drug reactions of the host animal became relevant in differentiating the range of optimal use for these pyrethroids.

Amidines

Important Compounds

Amitraz, cymiazole.

General Information

The formamidines are structurally related to octopamine. Since they mimic the action of this phenolamine in a number of insect preparations it was concluded that these compounds act via effects on octopamine sensitive adenylate cyclase (octopamine-receptors). In addition formamidines are reasonable potent inhibitors of monoamine oxidase (MAO) in cattle ticks and mammals. However MAO activity in insect nervous tissue is low and no consistent similarities or structure activity relationship have been observed between the biological effects of known MAO inhibitors and those caused by amidines in insects and ticks. It still remains to be established whether this action is causative of any of the various responses of veterinary or agricultural important insects and acarines.

Numerous biochemical targets have been suggested for formamidines, however on the basis of current knowledge the action on sites responsive to biogenic amines seem to be most likely. In animal health formamidines, in particular amitraz, displays a high acaricidal activity and offers an alternative to control organophosphorus and/or organochlorine and/or pyrethroid resistant ticks and mange mites of cattle, sheep and pigs.

Amitraz causes ticks to withdraw their mouthparts rapidly and fall off the host animal, which from the viewpoint of practical control of tick-born diseases is highly desirable.

Avermectins/Milbemycins

Important Compounds

Abamectin, doramectin, eprinomectin, ivermectin, selamectin, moxidectin, milbemycin-oxime.

General Information

Avermectins, milbemycins and their active derivatives inactivate ► [nematodes](#), arachnids and

some insects by disrupting their nerve transmission. Most of the studies have been performed with ivermectin.

In GABA sensitive fibres from insect skeletal muscles ivermectin induced increased chloride conductance which was reversible at low concentrations (nM range) but irreversible in μ M range. GABA insensitive muscle fibres produced only irreversible responses to ivermectin, particularly the drug inhibited chloride conductance gated by glutamate receptors in locust muscle fibres. These and other investigations led to the conclusion that this class of compounds act through their effects on glutamate gated chloride channels.

The activity against arthropods varies to some extent depending on the milbemycin or avermectin type of drug and the delivery method.

Insect Growth Regulators

Insect or acarid growth regulators may provide a complementary method to parasite control relying on adulticide drugs. Growth regulators often have a favourable safety margin which enables them to be used also in systemic applications either as in-feed products, boluses or tablets.

After uptake their presence in manure, body fluid or skin interrupts the life cycle of various ectoparasites. Growth regulators display their mode of action either by preventing development of eggs, larvae or nymphs (e.g., tick ► [Boophilus microplus](#)) directly on contact or by interfering with egg development and hatching after being ingested during feeding of adult females (e.g., flea: ► [Ctenocephalides felis](#)).

Since growth regulators only operate on a specific part of the ► [ectoparasite](#) life cycle they usually have little direct effect on the adult parasite population and achieve control after a longer period of time when compared to fast acting neuroactive compounds.

Growth regulators provide a valuable tool for long term control when used in conjunction with other arthropodicides which clear the host from adult parasite and final larval stages.

Triazine

The drug Cyromazine is an insect growth regulator which is still used to control blow fly strike and fly development in poultry manure. Cyromazine interferes with moulting and pupation and causes reduced growth of treated larvae. A direct effect on ► [chitin](#) biosynthesis has not been confirmed, but evidence has been presented that interference with ► [cuticle](#) sclerotisation and elasticity might be responsible for the antiparasitic effect of this substance.

Benzoylphenylureas

Important drugs are diflubenzuron, fluazuron, lufenuron, and triflumuron.

The exoskeleton of arthropods consists of different layers, of which typically the procuticle contains the amino sugar polysaccharide chitin, a major component of insect cuticle.

Nucleoside peptide antibiotics and benzoylphenylureas (BPUs) are the major groups of compounds acting primarily at chitin synthesis as target site.

For animal health indications only BPUs have been developed and commercialised internationally. Original studies of the mode of action of BPUs have implicated that synthesis and deposition of chitin are disturbed after application of BPUs.

Since these findings several hypotheses for their mode of action have been proposed, but the underlying biochemical mechanism still remains unclear. So far inhibition of precursor transport, proteolytic activation of chitin synthase zymogen, direct inhibition of chitin synthase, indirect hormonal effects and effects on cell membranes in combination with vesicle transport have been discussed as the primary mode of action.

The inhibition of cuticle deposition after BPU treatment results in death of larvae, pupae and non viable adults. In addition egg development and hatching are interrupted if particular systemically active BPUs are ingested during feeding of female ticks (fluazuron) or fleas (lufenuron). Even if growth regulators require more time to reduce ectoparasite populations they are useful tools, particularly in combination with compounds displaying an alternative mode of action, to control different life stages of ectoparasites.

Juvenoids

Important drugs are fenoxycarb, hydroprene, methoprene, and pyriproxyfen.

The development of arthropod parasites comprises an orderly series of stages in the course of which they become transformed from larval stages into an adult. This process involves a series of moults and a ► [metamorphosis](#) which can be disturbed with drugs which act similarly to insect ► [juvenile hormones](#).

The main effects contributing to insect control often depend on the target pest and the timing of application.

In the veterinary field juvenoids are particularly useful in controlling flea development either used in topical on-animal applications or in sprays to prevent hatching of fleas from companion animal surroundings.

► [Hygiene](#) pests such as various species of ► [mosquitoes](#), house flies and to a lesser extent cockroaches can be controlled with juvenoids, too. Due to their improved stability particularly fenoxycarb and pyriproxyfen are useful for these indications.

The exact mode of action of juvenoids has not been resolved so far. A number of factors other than receptor binding may influence the activity of a juvenoid significantly when applied at a sensitive stage in growth. Penetration through the cuticle and transport to the target tissue, rates of degradation and excretion, inhibition of the juvenile hormone (JH) degradation system as well as competitive binding to JH carrier proteins are still under evaluation.

Arylpyrazoles

Important Compound

Fipronil.

General Information

γ -Aminobutyric acid (GABA) is a major inhibitory transmitter at the neuromuscular junction not only in nematodes but also in insects and most likely in acarines, too. Upon binding of GABA to its receptor a rapid influx of chloride into the cell is induced which results in a hyperpolarisation of the membrane potential. In most cases an

inhibitory effect on the respective cell is the consequence of this GABA activity. In vertebrates two subtypes have been identified. GABA_A receptors which form a ligand gated chloride channel as well as contain modulatory sites for various drugs; and GABA_B receptors, G-proteins which display various effects on calcium and potassium channels. Most GABA receptors in insects resemble GABA_A subtype, but they are clearly distinct from the vertebrate GABA_A receptors. The GABA receptor is an important target for some older arthropodicides such as lindane cyclodiens but is also affected by fipronil, a new insecticide and acaricide which belongs to the chemical class of arylpyrazoles. This has been recently confirmed by cloning of a *Drosophila* GABA-gated chloride channel subunit using genetic mapping of a mutation which causes resistance against dieldrin (RdI). Fipronil was developed as an agrochemical and veterinary arthropodicide. In the veterinary field the compound is used for the treatment of fleas in dog and cats and ticks in dogs.

Chloronicotinyles

Important Compound

Imidacloprid.

General Information

Cholinergic synapses play a critical role in transmission in arthropods and nematodes. Recently a new drug, imidacloprid, was discovered displaying a new mode of action. Insecticides of this type act as agonists at the nicotinic acetylcholin receptor (nAChR) as was demonstrated by electrophysiological techniques and biochemical competition assays. The compound is highly effective against target insects, such as fleas or cockroaches but has virtually no effect on the mammalian nervous system. This might be explained by the fact that imidacloprid is not absorbed into the host animal bloodstream or internal organs and nAChRs from mammalian sources are much less or not at all sensitive to the agonistic action of insecticidal chloronicotinyles. In this context the fast killing of adult fleas on dogs and cats on contact not only

prevents re-infestation for a long period of time (at least 4 weeks) but also significantly reduces the occurrence of flea ► **allergy** dermatitis caused by flea saliva allergens.

Rotenone

Rotenone is a natural product derived from plant roots of *Derris* and *Lonchocarpus*. This drug is a highly effective inhibitor of complex I of the mitochondrial respiratory chain and inhibits NADH cytochrome c-reductase in nmole per mg protein range. The drug has largely been replaced by modern compounds, but is still used in combination products against ear mites and demodectic mange.

Benzylbenzoate

Benzylbenzoate is an old acaricidal drug which is useful for the treatment of sarcoptic mites in dogs.

Sulphur

Due to the availability of new and safer products nowadays the use of sulphur for mite treatment has been largely banned not only because of toxicological but also pollution concerns.

Arthropods Blood-Feeding Structures

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Arthropods possess different types of mouthparts, which help them to obtain their food the origin of which is species depending. Most common ones are biting mouthparts that tear food to pieces, blood-, lymph- or plant juice-sucking ones or those, which allow to feed by licking. All of

Arthropods Blood-Feeding Structures, Table 1 Construction of the piercing-proboscis and function of individual parts in blood-feeding insects and mites; compiled by Krenn and Aspöck (2012)

Agent	Proboscis formation			Function during feeding

Artyfechinostomum malayanum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Echinostomatid trematode of pigs and rats. Humans may become accidentally infected, if they eat raw infected water snails. The life cycle runs similar to that of *Echinostoma* species. They are characterized by 39–45 collar spines and of a large cirrus sack. Common species are *A. mehrai*, *A. malayanum*, and *A. surfrartyfex*.

Ascariasis, Man

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Pathology

Ascariasis is an infection with ► *Ascaris lumbricoides*, a large, lumen-dwelling nematode contracted by the ingestion of its larva via eggs (► *Ascaris*/Fig. 1). The larvae penetrate the small intestine wall and migrate through the lymphatics and blood stream to the liver, and then to the lungs where they enter the alveoli. There they pause for at least 2–3 weeks and molt, giving rise to allergic

Ascariasis, Man, Fig. 1 Targets and approaches for the control of ascariasis

bronchopneumonia in previously infected and sensitized individuals. Later, they wander up the bronchi and trachea, giving rise to bronchitis with bronchospasm, ► *urticaria*, and occasionally, larvae in the sputum. Most larvae are swallowed and grow to adulthood in the small intestine. The adult worms are up to 30 cm long and 4 mm wide, and give rise to mechanical problems because of their size and, especially in children to a severe nutritional drain, because of the worm number and mass. A temperature elevation to 39 °C, certain drugs, and some unknown influences may cause the worms to congregate, sometimes resulting in intestinal obstruction and migration out of the gut into the bile duct, esophagus, mouth, pancreatic duct or appendix, and occasionally the liver. The migration leaves necrotic tracts in the liver with hypersensitive inflammation produced by adults and eggs (► *Pathology*/Fig. 27A). Adult worms may perforate the intestine and pass out of the gut, leading to peritonitis.

Targets for Intervention

Eggs of *Ascaris lumbricoides* are not immediately infective after leaving the infected host. They

require a holding period in a suitable environment and become infective once second-stage larvae have developed in the eggs. Figure 1 shows the carrier and the infection cycle as targets of intervention. Control may be achieved by the detection and treatment of infected persons, safe disposal of feces, and improving agricultural ► [hygiene](#) and food hygiene.

Main Clinical Symptoms

► [Eosinophilia](#), ► [abdominal pain](#), ► [vomiting](#), enteritis, and ileus verminosus.

Incubation Period

Lung: 7 days, intestine: 3 weeks (however, 85 % of the patients remain symptomless).

Prepatent Period

2 months.

Patent Period

9–15 months.

Diagnosis

Microscopic determination of eggs in fecal samples (► [Ascaris](#)/Fig. 1).

Prophylaxis

Avoid eating uncooked vegetables and avoid human feces.

Therapy

Treatment see ► [Nematocidal Drugs, Man](#).

Ascaridia galli

Classification

► [Nematodes](#).

General Information

Specimens of this and related species grow up as females to a length of up to 12 cm inside the intestine of chicken and doves. A related species in turkeys leads to necrosis of the intestinal wall. The life cycle is monoxenous, i.e., the infection runs from bird to bird by ingestion of the $80 \times 50 \mu\text{m}$ -sized eggs. Each of which develops an infectious larva within 8–10 days after being excreted with the feces. The larvae – when hatched from the egg inside the intestine – enter the intestine wall for 3 weeks. After a total of 5–8 weeks maturity is reached and egg production starts. Pathogenesis is considerable, since bacteria superinfect the intestinal wall lesions. Anemia is common.

Treatment

Nematocidal Drugs.

Ascaridia Species of Birds

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

General Information

1. **Name:** Greek, *askaris* meaning worm in the intestine; *idios* meaning own; Latin, *gallus* meaning cock; *columba* meaning dove; English, bird ascarids.
2. **Geographic distribution/epidemiology:** Worldwide occurrence in many bird species (farmed or wild) – however, the life cycles and also clinical symptoms are mostly only poorly investigated.

Ascaridia Species of

Birds, Fig. 1 Light micrograph of eggs of different species of nematodes occurring in the feces of farmed birds and of two species of mites occurring inside the food. *FU* cleavage stage, *LA* larva, *Milbe* mite

3. Morphology/life cycle: Common species are:

- *Ascaridia galli* (chicken birds, geese):
♀ = 11 cm; ♂ = 7 cm
- *Ascaridia columbae* (doves, pigeons):
♀ = 9 cm; ♂ = 6 cm
- *Ascaridia dissimilis* (turkeys): ♀ = 9 cm;
♂ = 6–7 cm
- *Ascaridia compar* (chicken): ♀ = 9 cm;
♂ = 6 cm

These species appear as typical ascarids with a whitish slender body and diameters of up to 4 mm parasitizing predominantly in the small intestine of their hosts. The females

deponate the eggs unembryonated. They measure about 80–90 µm × 45–50 µm and possess a rather thick wall; however, their surface is smooth (Fig. 1f). The eggs of the different species cannot be used for species diagnostic. Outside of the body the larva 1 develops inside the eggshell within 10–14 days, and after 2 molts the infectious larva 3 stage is reached, which remains inside until a potential host ingests this egg. Often it occurs that earthworms (e.g., genus *Lumbricus*) swallow such eggs and thus may become paratenic hosts. If eggs with the larva 3 or infected earthworms are ingested by

birds, the larva 3 molts inside the intestine into the larva 4 and remains for 8–10 days inside the lumen of the small intestine. Starting from day 8 p.i., these larvae enter the mucous layer of the intestinal wall. After further 4–6 weeks, they leave the mucous layer and reach maturity inside the lumen. In chickens it takes 6–8 weeks and in doves 4–5 weeks, until mature worms produce eggs that can be found in the feces.

- 4. **Symptoms of disease:** Especially young animals show severe symptoms of the disease: diarrhea, loss of weight, loss of feathers, weakness, pale crest and other anemic symptoms, ileus verminosis, and eventually death starting already on the 8th day p.i. due to mass invasion of larvae into the mucous layer of the intestine.
- 5. **Diagnosis:** Microscopical determination of the eggs by help of concentration methods (► [flotation](#), ► [SAFC](#), ► [MIFC](#)). **Attention:** Eggs of *Heterakis* (Fig. 1e) look rather similar.
- 6. **Infection:** Oral uptake of larva 3 containing eggs or earthworms.
- 7. **Prophylaxis:** Regular elimination of the feces, so that there is no time to develop the larvae inside. Regular control of the feces in order to feed anthelmintics as soon as possible. Cleaning stables and/or cages with hot steam.
- 8. **Incubation period:** 3–8 days; symptoms occur due to larval invasions into the mucous layer of the intestine.
- 9. **Prepatent period:** About 5–6 weeks in *A. columbae* and 6–8 weeks in *A. galli*.
- 10. **Patency:** Probably lifelong.

- 11. **Therapy:** For treatment several compounds had been used successfully (e.g., flubendazole, levamisole). In addition to chemotherapy, a substitution of vitamin A, B, and B₁₂ plus minerals is recommended.

f female, m male

Ascaris, Fig. 1 Life cycle of ascarid worms (e.g., ► *Ascaris lumbricoides*, *A. suum*) of man and swine. 1–2 Adult worms (male 15–25 × 0.3 cm; female 25–40 × 0.5 cm) live in the small intestine of their hosts and feed (in general) on the liquid contents of the gut. Fertilized eggs are ovoid to spherical (45–75 × 35–50 μm), are surrounded by a thick, lumpy, mammillated shell and are usually uncleaved when passed in the feces (2). The shells of unfertilized eggs are thinner. 3–6 On the soil a period of about 10–40 days (dependent on the temperature) is needed to develop the second larval stage (L₂) inside the egg (some authors describe development until L₃). 7–8 After oral uptake of

infectious eggs, the larvae hatch in the intestine (in 3–4 h), enter the intestinal wall, pass through the liver and via heart to the lung, where finally the L₃ is formed. These third larval stages break into the air spaces of the lung and move up the trachea to the pharynx, where they are swallowed. In the intestine (reached around the 8th day after infection) the worms molt twice and mature, starting eight weeks after infection (prepatent period). This peculiar migration is considered as ► **phylogenetic reminiscence**. (a) anterior end; (b) intestine; AD adult worm, AL anlage of intestine, E esophagus, ES egg shell, IN intestine, L_{1–4} larval stages, LI lip, S sensory organ, SM small intestine

Ascaris lumbricoides

Ascaris was recently shown to possess hemoglobin. While the hemoglobin of the body wall resembles vertebrate myoglobin (~40.6 kDa), that of the perienteric fluid is an octomer (328 kDa) and has the highest affinity for oxygen of any known hemoglobins.

Life Cycle

Ascaris, Fig. 1. Human round worm, ► *Ascaris*, ► *Nematodes*.

Ascaris Species of Animals

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

General Information

1. **Name:** Greek, *askaris* meaning intestinal worm; *toxos* meaning arch or bow. Latin: *suus* meaning pig; *para* meaning similar, *equus* meaning horse, *leo* meaning lion. Greek: *prokyon* meaning star close to the star assemblage, *kyon* meaning dog, name for the raccoon.
2. **Geographic distributions/epidemiology:** Worldwide in many farm animals and in free-living animals.
3. **Morphology/life cycle:** There are several ascarids in animals, which live together or close to humans:
 - *Ascaris suum* (pigs) – ♀ up to 40 cm
 - *Parascaris equorum* (horses, equids) – ♀ up to 40 cm
 - *Toxascaris leonina* (dogs, cats) – ♀ up to 12 cm (see also *Toxocara* species of dogs)
 - *Baylisascaris procyonis* (raccoons, dogs) – ♀ up to 12 cm

Their life cycle is very similar to that of *Ascaris lumbricoides*. If humans ingest eggs of these species, the larvae wander within its body, but adults are not formed. Thus, conclusions derived from molecular biological data comparing *A. suum* and *A. lumbricoides* (of humans) that both are the same species are surely not true with respect to biological behavior and with respect to the results of Abebe et al. (2002), who demonstrated species-specific proteins in both species.

4. Symptoms of the disease (ascariasis, ascariasis):

1. During the phase of larval migration through the different organs of the body of the infected animals, the animals feed much less than normally and show weakness, with increased breathing, coughing, pneumonia, and a typical eosinophilia; eventually also the symptoms of **hepatitis interstitialis parasitaria multiplex** may occur. In pigs the liver appears with whitish dots (milk dots), which are reactions to wandering larvae (Fig. 1).
2. Adult worms induce loss of fitness and weight, diarrhea, icterus, or even **ileus verminosis**.
5. **Diagnosis:** Demonstration of the typical, thick-shelled eggs, which develop outside of the host, the infectious larva 2, which hatches from the egg after it is ingested by another or the former host (Fig. 2).
6. **Infection:** Oral uptake of eggs containing the larvae 2.
7. **Prophylaxis:** Regular removal of feces, which could contaminate the food or which would attract flies that are able to transmit mechanically infectious eggs onto food or mouthparts of the hosts. Disinfection of stables using hot steam.
8. **Incubation period:** 4 days (*A. suum*), 7 days (*P. equorum*), and 4–5 days (*T. leonina*, *B. procyonis*).
9. **Prepatent period:** 8–9 weeks (*A. suum*), 10 weeks (*T. leonina*, *B. procyonis*), and up to 15 weeks (*P. equorum*).
10. **Patency:** 1–3 years.

Ascaris Species of Animals, Fig. 1 Microphoto of a liver of a pig showing the typical milk spots as signs of an infection with *Ascaris suum*

Ascaris Species of Animals, Fig. 2 Micrograph of a typical *Ascaris* egg, the shell of which is ruptured, thus showing the larva

11. **Therapy:** There are many useful medications, based either on the modern broad-range benzimidazoles (given orally) or avermectines such as ivermectin and doramectin being injected or pour-on administered. Furthermore, there are used preparations containing piperazine, which, however, have no effects on wandering larvae.

Ascaris suum

Name

Greek: *ascaris* = worm; latin: *sus* = pig.

Important roundworm of pigs, Alimentary System Diseases, Swine; eggs are used to settle symptoms of Morbus-Crohn.

Ascarops

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of the worldwide occurring nematode family Spirocercidae. The species (e.g., *Ascarops strongylina*) lives in the stomach of their hosts and sucks their blood, leading to weight loss,

anemia, and bloody diarrhea. The larvae 3 are found inside beetles and cockroaches which are taken up with the food.

Incubation Period

Ten to thirteen days.

Prepatent Period

Six weeks.

Therapy

Nematocidal drugs.

Ascarops strongylina

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Spirocercid nematode (thick stomach worm) of swine reaching as female a size of up to 20 cm. Coprophagic beetles are intermediate hosts. The larvae 3 may also become included into transport hosts such as small mammals, birds, etc. The female and male worms live on the surface of the mucocutaneous layer of the stomach and may introduce hemorrhagic inflammations. Occasional infections of numerous humans have been described, too.

Treatment

► **Doramectin** (0.3 mg/kg/s.c.), ► **ivermectin** (0.3 mg/kg/s.c.), and nematocidal drugs.

Ascetospora

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Phylum containing peculiar spore-forming parasites of trematodes, mollusks, annelids, and crustaceans. The spores contain several cells, however, do neither contain polar capsules nor polar filaments. In general these parasites are not well studied. The species of this group belong to three classes: Paramyxidea, Marteilliidea, and Haplosporidea. Important genera are *Haplosporidium* (in molluscs and decapods), *Paramyxa* (in polychaetes), and *Marteilia* and *Bonamia* (in oysters). The spores were excreted by their hosts and then enter new hosts via instreaming saltwater. Having reached the new host, they become attached and the sporoplasm leaves via pores the spore. Inside the tissues new spores are formed that leave their host after destruction of the parasitized organ. Thus all species are very pathogenic for their hosts and lead to huge economic losses, e.g., in oyster farms.

This species (syn. *Ascocystis*, *Monocystis*, *Lankesteria*) is an aseptate gregarine species which parasitizes in *Aedes* and *Phlebotomus*

General Information

Among the ► [arboviruses](#), there is a group containing double-stranded DNA. These

ASF Viruses, Table 1 Arboviruses I. Double-stranded DNA viruses: African swine fever-like viruses (unnamed family) (spherical, with envelope)

Genus (group)	Species (selected)	Arthropod host	(Main) vertebrate hosts	Distribution	Disease in man	Disease in animals
African swine fever-like viruses	African swine fever viruses	Argasidae (<i>Ornithodoros</i>)	Domestic and wild swine, wart hogs, bush pigs, grant forest hogs	Africa	—	+ (depending on strain)

spherical viruses with an envelope are also called African swine fever-like (ASF) viruses.

Important Species

See Table 1.

Asfarviridae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Classification

Family of double-stranded DNA viruses with one genus with one species, transmitted by midges (family Ceratopogonidae).

Asiatic or Asian Theileriosis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Disease due to the infection with *Theileria orientalis* sensu strictu in Japan and South and East Asia.

Asklepios

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Greek god of the knowledge of healing. The Latin name is *Aesculapius*. A stick with a snake became the symbol of the “healing science” and of the professional physicians.

Aspiculuris

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of oxyurid nematodes of rodents in laboratories, e.g., *A. tetraptera*, which (like *Syphacia muris* and *S. obvelata*) lives in the colon and cecum. In contrast to the quick development of the larvae in the eggs of the human oxyurid ► *Enterobius vermicularis*, in ► *Syphacia* species of rodents, and in *Oxyuris equi* of horses, which depone their eggs outside of the anus, the development of the *Aspiculuris* larvae inside the excreted eggs is slow and needs 5–7 days. The worms of the 19 worldwide described species measure as females 5–7 mm in length and as

males 3–5 mm, while the width (0.2–0.3 mm) is very tiny.

The prepatent period of *A. tetraptera* takes 24 days. In general low infection rates run without considerable clinical symptoms, however, blood parameter may be changed, so that treatment is recommended especially in animals which are used for laboratory experiments. **Treatments** with 3–4 mg/kg ivermectin were successful, when four applications were done on 4 consecutive days with intervals of 3 days.

Aspiculuris tetraptera

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Nematode species of rodents inducing the oxyuridosis. These worms may occasionally infect humans, who work with laboratory rodents.

Aspidobothrea

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Group of tiny (max. 5 mm long) monogenean trematodes, which live as endoparasites in limnish

or marine snails, mussels, crustaceans, or even fish. This group is also known under the name ► *Aspidogastrea* (Fig. 1).

Aspidogaster conchicola

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Species of the monogenean worm group ► *Aspidogastrea*, which are characterized by a large ventrocaudal sucker (Fig. 1 A in ► *Aspidogastrea*.), which is also called ► *Baer's disc*. It stretches at the end of the individual development starting from the terminal end over the

whole ventral side. The eggs are excreted into water, where the ciliated, 0.1–0.2 mm long larvae (see Fig. 1 C in ► *Aspidogastrea*) hatch and swim around as so-called *Cotylocidium* larvae. The larvae of *A. conchicola* enter mussels as well (families Unionidae, Mutelidae, Sphaeriidae, Corbiculidae) but also prosobranchial snails. These larvae become mature in its first host (Fig. 1) and develop inside the organs of both sexes. Other species need obligatorily a second host (e.g., *Lobatostoma manteri*), parasitize first in snails and finally reach maturity in snail feeding fish (genus *Trachinolus*). Also turtles may become involved as second hosts. It is also known that larvae of the *Aspidobothrea* may live in the intestine of vertebrates, inclusively humans, if they have ingested infected raw molluscs or fish. Then the parasites live in the intestinal tractus, gall ductules, or in the gall bladder.

Aspidogaster limacoides

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This fluke species, which parasitizes, e.g., in the white bream *Blicca bjoerkna* occurring in the Danube river in Europe, is characterized as other members of the ► *Aspidogastrea* by a large ventral-terminal sucker. Larval development occurs in freshwater molluscs, however, without intramolluscan larval reproduction. This species possesses six medium-sized chromosome pairs. The first and the last pairs were two-armed, while the four remaining ones were one-armed; $2n = 12$.

Aspidogastrea

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Aspidobothrea.

Classification

Class of ► [Platyhelminthes](#).

General Information

The Aspidogastrea is a relatively small group, which is characterized by a very large hookless holdfast organ (ventral or Baer’s disc, ► [opisthaptor](#)), which, in adult worms, covers nearly the whole ventral side (Fig. 1a). The Aspidogastrea are typically endoparasites of many molluscs, elasmobranchs, teleosts, turtles, or decapod crustaceans (Table 1) and are not host-specific. Their development occurs as ► [metamorphosis](#) via larval stages (Fig. 1b, c); in general no intermediate host is needed; however, larvae may continue their development in different hosts. With respect to host specificity, their parasitism is apparently not very specialized, since it is not uncommon to find an aspidogastrea in the gut of a fish, although it may normally parasitize a mollusc.

Important Species

See Table 1.

Life Cycle

See Fig. 1a–c.

Aspidogastrea, Table 1 Some common species of the Aspidogastrea (syn. Aspidobothrea)

Species	Length (mm)	Host	Habitat
<i>Aspidogaster conchicola</i>	3	Freshwater clams Reptiles Fish Snails	Pericardial cavity Intestine Intestine Visceral mass
<i>Lophotaspis vallei</i>	5	Marine turtles Snails Clams	Esophagus, stomach Mantle cavity Pericardial cavity
<i>Multicotyle purvisi</i>	10	Snails Turtles	Pallial complex Intestine
<i>Stichocotyle nephropis</i>	115	Lobsters Rays	Wall of intestine Gallbladder
<i>Macraspis elegans</i>	15	Ratfish	Gallbladder
<i>Cotylaspis insignis</i>	2	Freshwater clams	Kidney, mantle cavity

<i>Rugogaster hydrolagi</i>	15	Ratfish	Rectal gland

Aspidogastrea,

Fig. 1 (a–c) Life cycle stages of *Aspidogastrea* (seen from ventral side).

(a, b). ► *Aspidogaster conchicola*. (a) Adult worm (2–3 mm long) from kidney of clams (Lamellibranchiata, Unionidae) or from the intestine of snails, fish, and reptiles. Excreted operculated eggs are embryonated and contain a creeping, nonciliated larva (b), which grows to the adult stage by gradual transformation. (c). *Multicotyle purvisi*, ciliated free-swimming larva; adults reach 10 mm in length and occur inside the pallial complex of snails (*Pila*) or in the intestine of snail-eating turtles. CF ciliated field, CI ► cilia, DO development of ► opisthaptor, IN intestine, LA lateral larval glands, LS larval anterior sucker, M mouth, NE nephridioporus (seen from ventral side since it opens dorsally), S ventral sucker (= Baer's disc)

**Morphology**

In the ► *cotylocidium* larva as well as the adult worms the external surface of the tegumental membrane shows a PAS-positive, filamentous surface coat, e.g., in adult *Aspidogaster conchicola* – a parasite of freshwater clams of the genera *Unio*, *Anodonta*, and *Gonidea* – it has a thickness between 100 and 300 nm. The sexual organs are diagrammatically depicted in Fig. 1 of ► *Aspidobothrea* (syn. *Aspidogastrea*).

Ataxia

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Disturbed control of body motions, which may be related to other reasons due to brain infections with ► *Toxoplasma gondii* or cysts and cysticerci of ► *Echinococcus Species*.

Atomic Force Microscopy (AFM)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The so-called atomic force microscope has been developed from the group of Binnig and Rohrer at IBM in Zürich, Switzerland, after the so-called scanning-tunneling microscope (STM), which is able to give sharp pictures of surfaces with high conductivity. In contrast to STM, the atomic force microscope is able to dissolve the surfaces of biological materials (even living cells), since it does not require a highly conductive surface. Thus, nanometer-resolution images are possible of structures of living cells in gaseous and liquid environments.

Atoxyl

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The French chemist and pharmacist Antoine Béchamp (1816–1908) synthesized an arsenic compound (being later described by Paul Ehrlich as aminophenyl arsenic acid) that he named Atoxyl which should be up to 50 times less toxic than pure arsenic acid. Since the British Empire enlarged around 1900, its influence on African countries where trypanosomiasis (= sleeping sickness) was spreading a medicament against this disease was highly wanted and thus intense research was started. The English researchers, at the famous Liverpool School of Medicine, HW Thomas and A Breinl (cited by Boyce [1907](#)) reported in 1905 a successful treatment of animals (rabbits) suffering from African trypanosomiasis, if high dosages of Atoxyl were administered. Thus they proposed to treat humans continuously as well with such high doses. This was the reason why ► [Robert Koch](#) just after having received the Nobel Prize for Physiology or Medicine in 1905 headed in 1906 on an expedition to the German “colony” in East Africa. After very successful single treatments, he started there a broad spectrum treatment of the so-called Sese islands,

which were situated within the Lake Victoria. It was noted that the clinical symptoms of treated persons decreased in very short time, but their blood was not yet free from parasites. Therefore the dose was somewhat increased in order to avoid relapses, when patients (who felt to be cured) left in secrecy the clinical camp. This increase led to the fact that about 2 % of the patients treated with very high doses were blinded via atrophy of the optic nerve. However, without any treatment the disease is practically fatal in all cases. At the same time Paul Ehrlich asked his coworker Alfred Berthelm to synthesize several variations of Atoxyl derivatives. The 606th variation (arsphenamine) was not effective against trypanosomiasis, but in 1909 the Japanese Sahachiro Hata and Paul Ehrlich showed that this compound is highly effective against the agents of the so-called human syphilis – the bacteria *Spirochaeta* (syn. *Treponema*) *pallida*, which was one of the most spread emerging diseases at these times. This product – originally developed against trypanosomiasis – was now the big success against syphilis and became marketed as Salvarsan® by Farbwerke Frankfurt-Hoechst (Germany) until the time the antibiotics arose and Penicillin replaced Salvarsan. This, however, took 40 years until the late 40s and early 50s of the twentieth century.

Atrichia (Syn. Atrichosis)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Disease during which hairless regions occur, e.g., as consequence of a parasitic infection. Allergic reactions due to flea bites lead also to this symptom as well as infections with ► *Sarcoptes scabiei* or ► *Demodex folliculorum*.

Atrichopogon

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of midges (► *Ceratopogonidae*).

Attractans

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Compounds or odor that attracts blood-sucking or mating arthropods and several other but eyeless species (e.g., some ticks, termites).

Auchmeromyia

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The calliphorid fly *A. senegalensis* (syn. *A. luteola*) belongs to those flies introducing myiasis (Figs. 1 and 2). Its common name is Congo floor maggot; it does not burrow in the skin, but it sucks blood of sleeping humans or animals. This activity is referred to as “sanguinivorous myiasis.”

Auchmeromyia, Fig. 1 *Auchmeromyia senegalensis*; blood sucking larva

A

Auchmeromyia, Fig. 2 *Auchmeromyia senegalensis*; adult fly with folded and unfolded wings

Auditory Ability

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The males of many Culicidae are able to “hear” the wing beat of females (about 250–350 Hz) via the scolopids of the Johnston organ at the second segment of the antennae and are thus attracted. Females are unable to percept the wing beat of males (350–500 Hz) and thus unable to avoid them, as is claimed by producers of piping apparatuses to repel biting females.

Australamphilina elongata

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Species of ► *Cestodaria* within the body cavity of the Australian tortoise *Chelodina longicollis*.

Austroilharzia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of bird schistosome species (e.g., *A. terrigalensis*, *A. variglandis*).

Austroconops

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of ► *Ceratopogonidae*. The only species of this genus (*A. macmillanii*) bites during

daytime in Western Australian humans and animals.

Austroleptis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of the snipe flies of the family Rhagionidae in Australia; they are also attacking humans.

Austrosimulium

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of bloodsucking simuliid Nematocera in Australia and New Zealand, vectors of onchocerciasis (e.g., *Onchocerca* of cattle).

Autochthonous

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *autos* = self; *chton* = place, spot.

This term describes, e.g., the existence of typical local agents of disease.

Autochthony

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The name derives from the Greek terms *chtono* = place and *autos* = self. It means that a plant/animal/parasite develops at a given place since long and has not been imported recently from another region. For example, the tick *Ixodes ricinus* is autochthonous in Germany; *Dermacentor reticulatus* is allochthonous (► [Allochthony](#)).

Autocid Technique

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This method, which is also described as ► “sterile male technique”, works by setting free sterilized males (from cultures) in a given region. These males are still active in mating, but females then do not produce progeny. Using this technique, e.g., the flies *Cochliomyia hominivorax* (screw worm) and the tsetse fly *Glossina palpalis* had been eliminated in some regions, where this measurement had been employed.

Autoclavation

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Sterilization of equipment by hot steam at 121 °C.

Autogamy

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Fusion of gametes originating from one individual (e.g., in *Taenia* – tapeworms).

Autogeny

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Egg production in some females ► [Culicidae](#) (e.g., genus *Toxorhynchites*) without preceding blood meal.

Autoimmunity

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Repeated contacts of humans or animals to certain molecules may lead to constantly increasing wrong-directed allergic reactions, which even may end in shock syndromes, among sensitized and/or insensible individuals.

Autoinfection

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *autos* = self. Latin: *infection* = infection.

This term describes the process when a host reinfects itself with a given agent of disease.

Autolysosome

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Type of secondary ► [lysosome](#) which is involved in the disintegration of cellular waste material, thus providing the function of disposal of debris.

Autophagy

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

From Greek *autos* = self; *phagein* = feeding.

This phenomenon was described also in protozoans (as autophagy-associated death), which was found linked to nutrient limitation, e.g., in ► [Apicomplexa](#) such as ► [Toxoplasma gondii](#) and *Plasmodium* species.

Babesia

Britta Petersen and Jabbar S. Ahmed
Division of Veterinary Infection Biology and
Immunology, Research Center Borstel,
Programme Priority Infection Biology, Leibniz
Centre for Medicine and Biosciences, Borstel,
Schleswig-Holstein, Germany

Babesia parasites, the causative agent of babesiosis, are transmitted by ticks and are able to invade

the red blood cells of the vertebrate hosts. They cause a febrile disease of domestic and wild animals characterized by an extensive erythrocytic lysis leading to anemia, icterus, and hemoglobinuria and can be fatal. *Babesia* parasites are among the most widely distributed blood pathogens with a considerable economic, veterinary, and medical impact worldwide. In the last years, it became evident that certain *Babesia* species are of zoonotic importance.

Taxonomy

Taxonomic classification places the genus *Babesia* in the phylum Apicomplexa, Levine 1970, class Sporozoa Leuckart 1879; also called Aconoidasida, and the order Piroplasmida (Wenyon 1926; Homer et al. 2000) (Fig. 1).

Phylum: Apicomplexa
Class: Sporozoa
Order: Piroplasmida
Family: Babesiidae
Genus: *Babesia*

Babesia species are characterized by intraerythrocytic forms; have apical complex organelles, a merogonic stage within the vertebrate host erythrocytes, and a sexual development; and show the formation of sporozoites within the invertebrate host (Homer et al. 2000).

Closely related to *Babesia* are *Theileria*. The main distinction between the two genera is

Babesia, Fig. 1 Hypothetical tree of Apicomplexa. Three principal parasitic groups are colored and their life cycle indicated, as well as *Cryptosporidium* that likely emerged from within gregarines. Numbers on branches and

thickness indicates diversity (i.e., named species) (Source: Slapeta (2011b) Creative Commons Attribution-NonCommercial License – Version 3.0)

the absence of the extra-erythrocytic asexual multiplication (schizogony) in *Babesia*. Moreover *Babesia* parasites, unlike *Theileria*, show transovarial transmission (Homer et al. 2000; Ahmed et al. 2006; Votýpka 2011; Chauvin et al. 2009). Recent investigations revealed that *B. equi* and *B. microti* do not fit to the genus *Babesia* as both species show intra-lymphocytic parasite stages (Mehlhorn and Schein 1998; Schein et al. 1981). These observations were confirmed by sequence analysis of 18S rRNA gene (Allsopp et al. 1994). Accordingly both species have been reclassified as *Theileria*. (See also chapter “► *Theileria Species*.”) Progress in *Babesia* spp. identification has also led to the recognition of new species within the genus. Thus, e.g., *B. canis* was previously described as a single species, but has actually been split into at least three distinct species or subspecies: *B. c. canis*, *B. c. rossi*, and *B. c. vogeli* (Chauvin et al. 2009).

Referring to the size of the merozoites produced, *Babesia* spp. are divided into two groups with large *Babesia* (e.g., *B. bigemina*, *B. canis*, *B. major*) and small *Babesia* (*B. bovis*, *B. divergens*, *B. gibsoni*) (Homer et al. 2000; Chauvin et al. 2009).

Life Cycle

Babesia spp. accomplish their life cycle in a vertebrate host (mostly mammals but also birds) and in an invertebrate host (mostly Ixodidae but very rarely also soft ticks) (Homer et al. 2000; Šlapeta and Morin-Adeline 2011a, b; Chauvin 2009; Mehlhorn and Schein 1984; Gohil et al. 2010) (Fig. 2).

Development in Vertebrate Hosts

After being inoculated by the tick, sporozoites penetrate directly into the erythrocytes (Šlapeta and Morin-Adeline 2011b). In contrast to *Plasmodium*

Babesia, Fig. 2 Life cycle of *Babesia* spp. (Adopted from Mehlhorn and Pikarski 1998) 1 Sporozoites in saliva of feeding tick. 2–5 Asexual reproduction in erythrocytes of vertebrate host (dog) by binary fission, producing merozoites (5) which enter other erythrocytes. When merozoites are ingested by a tick (5.1), they become digested inside the gut (5.2). 6 Some merozoites become ovoid gamonts. 7, 8 After ingestion into the tick's intestinal cells, the ovoid gamonts form protrusions and thus appear as ray-bodies (8). Fusion of two uninucleate ray-bodies (gametes). 10 Formation of a zygote. 11–14 Formation of a single kinete from a zygote inside the inner vacuole. The kinete leaves the intestinal cell and enters cells of various organs (including the eggs) of the vector ticks. 15–18 Formation of several kinetes (sporokinets). This process is repeated

(15–18) and also proceeds in eggs of ticks. The infection is thus transmitted to the next generation of ticks (i.e., transovarial transmission). 19–21 Some of the kinetes penetrate cells of the salivary glands, where a large multinuclear sporont (YS, ES) is formed (inside the hyper-trophic host cells) finally giving rise to thousands of small sporozoites (SP), which are injected during the feeding act (i.e., transstadial transmission). CY cytomere (uninucleate), DE digested erythrocyte, DK developing kinete, E erythrocyte, ES enlarged sporont (forming sporozoites), GP growing parasite (polymorphic stage), HC nucleus of host cell, IV inner vacuole, N nucleus, NH nucleus of host cell, R raylike protrusion, SP sporozoite, T thornlike apical structure, YS young sporont. Schizo-, gamo-, sporogony are English terms

spp. or *Theileria* spp., all the parasitic stages develop in the red blood cells. Inside the erythrocytes, the parasite feeds off the host cell and transforms into trophozoites which produce merozoites by binary fission (Chauvin 2009; Šlapeta and Morin-Adeline 2011b). Each merozoite invades a new erythrocyte. This multiplication process runs asynchronously, so that various stages of the parasite can be seen in the bloodstream at the same time.

Development in the Invertebrate Host

Once a tick ingests *Babesia*-infected erythrocytes, some parasites are taken by the tick epithelial cells and develop to amoeboid cells (Lee et al. 2000; Ribeiro et al. 2009) and then evolve into gametocytes (Chauvin et al. 2009; Mehlhorn and Shein 1984; Šlapeta and Morin-Adeline 2011b). The piroplasms begin to develop into the so-called Strahlenkörper or ray bodies (Mehlhorn and Shein 1984), which are believed to be the gamonts (Chauvin et al. 2009). The fusion of gametes inside the lumen of the tick's digestive tract leads to the stage of the diploid zygote and then transforms to ookinete which infects other tissue of the tick (Homer et al. 2000; Bock 2004; Chauvin et al. 2009). It is assumed that meiosis takes place in this stage, indicating the beginning of sporogony (Chauvin et al. 2009). As mentioned above, *Babesia* spp. show a transovarial transmission, when the ookinetes invade the female tick's ovary as this results in many *Babesia*-infected eggs (Chauvin et al. 2009). Transstadial transmission of the parasite is likewise happening as sporogony takes place in all stages of the tick's life cycle and thus an infection acquired during one life stage is passed on to the next one. Sporogony continues and numerous kinetes are produced. Once a parasite has infected the salivary acini, a multinucleate but undifferentiated sporoblast is formed (Homer et al. 2000). After a tick attaches to a host, the sporoblast differentiates further to sporozoites, which infect the vertebrate host after the tick sucks blood (Homer et al. 2000; Chauvin et al. 2009; Mehlhorn and Shein 1984; Šlapeta and Morin-Adeline 2011b). In all *Babesia* species, the formation of sporozoites usually only begins when a tick attaches to a vertebrate host (Mehlhorn and Schein 1984; Bock 2004).

Symptoms and Pathogenesis of Babesiosis

Symptoms and pathogenesis of *Babesia* infections are generally dependent on the dose of the inoculated parasites, the susceptibility of the host, and the virulence of the parasite strain. Incubation time varies from 1 week to several weeks (Imes et al. 2011). The parasite causes the destruction of erythrocytes. Clinical signs of the disease include fever and anemia. Furthermore anorexia as well as lethargy, diarrhea, cachexia, tachycardia, hemoglobinuria and hypotensive shock syndrome, vasodilatation, hypotension, increased capillary permeability, oedema, vascular collapse, coagulation disorders, endothelial damage, and circulatory stasis may occur (Ahmed 2002; Bock et al. 2004).

Animals which recover from the infection become carriers of the parasite without showing apparent clinical signs. The disease may, however, relapse under stress conditions. Chronic infections occur often without apparent hemoglobinuria.

Bovine Babesiosis

There are a number of different *Babesia* species that affect bovines throughout the tropical and subtropical areas of the world. The most important species are *B. bovis*, *B. bigemina*, and *B. divergens*, of which *B. bovis* is the most pathogenic species (Bock et al. 2004). No or little pathogenicity occurs due to *B. major* and *B. occultans* infection (Vogl 2004). Further species occurring in bovines are *B. jakimovi* and *B. ovata* (Bock et al. 2004; Vogl 2004).

1. *Babesia bovis*

Tick vectors for this *Babesia* species are *Boophilus annulatus*, *B. microplus*, *Rhipicephalus bursa*, *Ixodes ricinus*, and *Ixodes persulcatus*.

B. bovis has a wide distribution ranging from Asia, Africa, Australia, Central and South America, and Europe.

B. bovis is considered to be the most pathogenic species among the bovine infective *Babesia* and belongs to the most important

tick-transmitted blood parasites (Uilenberg 1995). The host spectrum of this parasite in general includes the genera *Bos*, *Bubalus*, *Syncerus*, and *Bison* (Vogl 2004).

With its average size of $2 \times 1,5 \mu\text{m}$ *B. bovis* belongs to small *Babesia* (Vogl 2004). The virulence of this pathogen varies and is also dependent on the host condition. Hence splenectomized animals have a higher risk of developing severe disease than animals with an intact spleen (Wright and Goodger 1988). Calves are more resistant against infections with *B. bovis* until they are 9 months old (Vogl 2004; Levy et al. 1982).

Infections with *B. bovis* often result in high mortality rates in affected animals. In acute forms parasitized erythrocytes are sequestered in the microcapillary beds of the brain and lung resulting in cerebral babesiosis and respiratory distress syndrome associated with neutrophil infiltration into the lung capillaries.

2. *Babesia bigemina* (Smith and Kilborne 1893)

Babesia bigemina is transmitted by ticks of the genera *Boophilus*. Recorded vectors are: *Boophilus microplus*, *Boophilus annulatus*, and *Boophilus decoloratus* (Vogl 2004)

Babesia bigemina has a wide distribution ranging from Asia; Africa; Australia; Central, South, and North America; and Europe.

With an average size of $4,5 \times 2 \mu\text{m}$, *B. bigemina* belongs to the large *Babesia* species, which is characterized by the frequent occurrence of pair-wise alignment of merozoites in erythrocytes, hence the name “bigemina.” Merozoites can however also show a round, oval, or unregulated appearance (Levine 1988).

The disease caused by this parasite is also known as “Texas cattle fever” or “redwater fever.” In cattle, the parasite can cause massive destruction of the red blood cells leading to severe anemia and hemoglobinuria, which can lead to the death of a cow within a week. High levels of mortality can occur in susceptible breeds. Clinical signs are similar to those of *B. bovis* infection with exception to neurological symptoms.

B. bigemina affects members of the genus *Bos*, such as *Bos taurus* and *Bos indicus*. Water

buffalo (*Bubalus bubalis*) and African buffalo (*Syncerus caffer*) and the American bison (*Bison bison*) are also susceptible (Kuttler 1988).

3. *Babesia divergens* (M’Fadyean and Stockman 1911)

B. divergens is characterized by hemoglobinuria, anemia, fever, and diarrhea. *B. divergens* belongs to the small *Babesia* species and is considered to be highly pathogenic.

B. divergens is transmitted by *Ixodes ricinus* (Vogl 2004). The distribution of this parasite includes North and West Europe (Vogl 2004; Euzeby 1990). There are references on its occurrence in Italy (Georges et al. 2001), Greece (Papadopoulos et al. 1996), and Tunisia (Bouattour and Darghouth 1996).

4. *B. major* (Sergent et al. 1926)

B. major is a large *Babesia* transmitted by *Haemaphysalis punctata* and *Haemaphysalis longicornis* and causes a mild infection. It has been described in Europe, the area of the former Soviet Union, and China (Vogl 2004).

Small Ruminant Babesiosis

A number of *Babesia* species capable of infecting small ruminants have been described, many of which are highly pathogenic for small ruminants. Among those, *B. ovis* and *B. motasi* are considered to be the most important species.

1. *B. ovis*

B. ovis occurs in Southern Europe, former Soviet States, Northern Africa, Middle East, and Asia (Melani et al. 2006; Hashemi-Fesharki et al. 1997). *R. bursa* is the most known vector of *B. ovis* (Meliani et al. 2006; Hashemi-Fesharki et al. 1997). In addition, *R. turanicus*, *R. evertsi evertsi*, *H. a. anatolicum*, and *H. a. excavatum* may function as vector of *B. ovis* (Meliani et al. 2006; Bakheit et al. 2007).

Babesia ovis infection in small ruminants is characterized by fever, anemia, icterus, and hemoglobinuria. Mortality in susceptible

hosts ranges from 30 % to 50 % (Meliani et al. 2006; Hashemi-Fesharki et al. 1997).

2. *B. motasi* infection shows a moderate virulence. *B. motasi* is transmitted by *Haemaphysalis* ticks. *B. motasi* is recognized as pathogenic for small ruminants. An acute infection is manifested by anorexia, fever, fast and audible heart beats, pallor of the mucous membranes, icterus and hemoglobinuria, abdominal pains, diarrhea, prostration, and death.
3. *B. species* (China): A number of unclassified *Babesia* parasites infecting small ruminants have recently been reported in China and temporarily been called *Babesia* spp. (China). These parasites appear to be most closely related to *B. motasi*. However, in contrast to *B. motasi*, they are transmitted by *Haemaphysalis longicornis* and are highly pathogenic for goats and sheep.

Equine Babesiosis

Equine babesiosis occurs in Africa, Europe, Asia, South and Central America, and the southern USA, caused by *B. caballi* and transmitted by ticks of the genera *Rhipicephalus*, *Dermacentor*, and *Hyalomma*.

Babesiosis of Dogs

Babesia infections in dogs vary from mild, transient illness to acute form, which can result in death.

Babesia canis infection has been reported in dogs from most regions of the world and is caused by the following subspecies: *B. canis canis*, *B. canis vogeli*, and *B. canis rossi*.

The vector tick of *B. canis canis* in Europe is *Dermacentor reticularis*. *B. canis vogeli* is transmitted by *Rhipicephalus sanguineus* and *B. canis rossi* by *Haemaphysalis leachi* in South Africa.

Another important *Babesia* of dogs is *B. gibsoni* which causes a chronic disease with progressive severe anemia and is transmitted by *Haemaphysalis bispinosa* and *Haemaphysalis longicornis* (Schoeman 2009).

Babesiosis in Pigs

A severe disease due to infection with *Babesia trautmanni* in pigs has been reported in Europe and Africa. Although with a limited distribution, *B. perroncitoi* has a similar pathogenicity. The vector of these two *Babesia* parasites has not been clarified.

Human Babesiosis

Although with a limited distribution in Europe, human cases of babesiosis have been reported in immunocompromised individuals or splenectomized patients to be due to *B. divergens*.

Distribution

Major *Babesia*, their vectors, and distribution are shown in Table 1.

Diagnosis

The demonstration of the pathogen in thin or thick Giemsa-stained smears of peripheral blood or draining lymph nodes is confirmatory. In addition, serological tests like indirect hemagglutination, complement fixation tests, and enzyme-linked-immunosorbent assay (ELISA) have been established for a number of *Babesia* species (Bakheit et al. 2007). Molecular diagnostic tools have also been successfully developed and applied for the detection and differentiation of *Babesia* parasites (Bock 2004).

Vaccination

Live attenuated vaccines for *B. bovis* and *B. bigemina* have been developed and applied in many countries such as Australia, Argentina, South Africa, Brazil, and Israel. It is assumed that attenuation through passaging the parasite in vitro culture results in enrichment of less virulent parasite populations (Bock et al. 2004).

Babesia, Table 1 Major *Babesia* species, their vectors, known distribution, and domestic hosts (Adopted from Bock et al. (2004) and Gray et al. (2009))

Babesia species	Major vectors	Known distribution	Domestic species affected	Human infections reported
<i>Babesia bigemina</i>	<i>Boophilus microplus</i> , <i>Boophilus decoloratus</i> , <i>Boophilus annulatus</i> , <i>Boophilus geigyi</i> , <i>Rhipicephalus evertsi</i>	Africa, Asia, Australia, Central and South America, Southern Europe	Cattle, buffalo	
<i>Babesia bovis</i>	<i>Boophilus microplus</i> , <i>Boophilus annulatus</i> , <i>Boophilus geigyi</i>	As for <i>Babesia bigemina</i> , but less widespread in Africa	Cattle, buffalo	
<i>Babesia divergens</i>	<i>Ixodes ricinus</i> , <i>Ixodes persulcatus</i>	North and West Europe, Spain, Great Britain, Ireland	Cattle	Yes
<i>Babesia major</i>	<i>Haemaphysalis punctata</i>	Europe, north-west Africa, Asia, Eastern Asia	Cattle	
<i>Babesia ovata</i>	<i>Haemaphysalis longicornis</i>	Eastern Asia	Cattle	
<i>Babesia ovis</i>	<i>Rhipicephalus bursa</i>	Southern Europe, former Soviet States, Northern Africa, Middle East and Asia	Sheep and goat	
<i>Babesia motasi</i>	<i>Rhipicephalus bursa</i> , <i>Haemaphysalis punctata</i>	Southeastern Europe, north Africa, Asia	Sheep and goat	
<i>Babesia caballi</i>	<i>Dermacentor</i> spp., <i>Haemaphysalis</i> spp., <i>Hyalomma</i> spp.	Africa, South and Central America, southern USA, Europe, Asia	Horses, mule, donkey	
<i>Theileria (Babesia) equi</i>	<i>Rhipicephalus</i> , <i>Dermacentor</i> , and <i>Hyalomma</i>	Southern Europe, Asia, Africa, Cuba, South and Central America, and certain parts of the southern USA	Horses, mule, donkey	
<i>Babesia canis</i>	<i>Rhipicephalus sanguineus</i>	Southern Europe, north America, Asia, Africa, Australia	Dog	
<i>Babesia gibsoni</i>	<i>Haemaphysalis</i> spp., <i>Rhipicephalus sanguineus</i>	Africa, Asia, Europe, north America	Dog	
<i>Babesia trautmanni</i>	<i>Rhipicephalus</i> spp.	Southern Europe, former USSR, Africa	Pig	
<i>Theileria (Babesia) microti</i>	<i>Ixodes scapularis</i> , (Germany: <i>Ixodes ricinus</i> ?, Japan: <i>Ixodes ovatus</i> ?)	Northeast, Upper Midwest USA (Germany, Japan, Taiwan)	Reservoir hosts: rodents, shrews	Yes
<i>Babesia venatorum</i>	<i>Ixodes ricinus</i>	Austria, Italy, Germany	Deer	Yes

Immune Response

Both cellular and humoral immune responses are operating during the course of a *Babesia* infection. The resolution of acute *B. bovis* infection in naive animals is largely achieved by activation of the innate immune response, activation of macrophages by IFN-gamma resulting in killing of the organisms by phagocytosis, and production of nitric oxide (NO) (Brown et al. 2003).

On the other hand, parasite-specific CD4+ T cells play also an essential role in protection against *Babesia* infections (Brown et al. 2003). Cytokines produced by these cells activate macrophages to secrete TNF-alpha, IL-18, and IL-12. The latter activates natural killer (NK) cells to produce IFN- γ (Brown et al. 2003). During the course of a *Babesia* infection, antibodies are produced which can neutralize sporozoites or merozoites (Hines et al. 1989).

Babesia Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

This genus of piroplasms (Protozoa, Alveolata, Apicomplexa = former Sporozoa) was named honoring the Romanian pathologist Victor Babès (1854–1926), who first described (1888) these parasites, which are very important agents of diseases in humans and especially in farmed animals.

Important Species

Table 1 lists a spectrum of species which are more or less well described. Some of them, however, have a doubtful, systematic position. For

example, the former species *B. equi* has already been transferred by Mehlhorn and Schein (1998) to the genus ► *Theileria* due to the existence of a typical schizogony in the lymphocytes of horse before the further asexual reproduction

Babesia Species, Table 1 *Babesia*. Important species of the genus *Babesia*

Species	Vector species	Vertebrate host	Size in erythrocytes (µm)	Geographic distribution
Significant Babesia species				
<i>B. bigemina</i>	<i>Boophilus</i> spp.	Cattle, water buffalo, wild ruminants	5 × 2	Southern Europe, Central and South America, Africa, Asia, Australia
<i>B. bovis</i>	<i>Boophilus</i> spp., <i>Ixodes</i> spp., <i>Rhipicephalus bursa</i>	Cattle, water buffalo, wild ruminants	2.5 × 1.5	Southern Europe, Central and South America, Africa, Asia, Australia
<i>B. divergens</i>	<i>Ixodes ricinus</i> , <i>I. persulcatus</i>	Cattle, wild ruminants, humans	1.1 × 1.0	Europe, North Africa, Turkey
<i>B. major</i>	<i>Haemaphysalis punctata</i> , <i>Haemaphysalis longicornis</i>	Cattle	3 × 1.5	Western and Southern Europe, Great Britain, USA, Africa, China
<i>B. ovata</i>	<i>Haemaphysalis punctata</i> , <i>Haemaphysalis longicornis</i> , appears very similar to <i>B. major</i> and occurs in Asia	Cattle	3 × 1.5	Asia
<i>B. motasi</i>	<i>Haemaphysalis</i> spp., <i>Rhipicephalus bursa</i>	Sheep, goats	4 × 2.0	Southern Europe, Middle East, Southern Russia, Africa, Asia
<i>B. ovis</i>	<i>Rhipicephalus bursa</i> , <i>Haemaphysalis punctata</i>	Sheep, goats	2 × 1.5	Southern Europe, Middle East, Southern Russia, Africa, Asia
<i>B. caballi</i>	<i>B. equi</i> of horses was transferred to the theilerians	Horses, mules, donkeys, <i>Equus burchellii</i>	4 × 2.5	Europe, Asia, Africa, America, Australia
<i>B. canis vogeli</i> <i>B. canis rossi</i> <i>B. canis canis</i>	<i>Rhipicephalus sanguineus</i> , <i>Haemaphysalis leachi</i> , <i>Dermacentor reticulatus</i>	Dogs, other wild canines, fox	5 × 2.5	Tropics, subtropics South Africa, Europe, North Africa
<i>B. trautmanni</i>	<i>Rhipicephalus</i> spp.	Pigs	4 × 2.5	Southern Europe, Africa
<i>B. herpailuri</i>	?	<i>Felis silvestris</i>	3 × 2.2	Southern America
<i>B. pantherae</i>	?	<i>Felis silvestris</i> , <i>Panthera leo</i>	2.5 × 1.5	Africa

(continued)

Babesia Species, Table 1 (continued)

Species	Vector species	Vertebrate host	Size in erythrocytes (µm)	Geographic distribution
Small Babesia species of doubtful systematic position				
<i>B. (syn. Microbabesia) gibsoni</i>	<i>Haemaphysalis bispinosa</i> , <i>Rhipicephalus sanguineus</i>	Canidae including dogs, fox, and other wild canines	1.2–2.1	Asia, Africa, India, Japan
<i>B. microti</i> group	<i>Ixodes</i> species	Rodents, raccoons, humans	1–2	Europe, North America
<i>B. felis</i> (syn. <i>Achromaticus felis</i>)	<i>Haemaphysalis leachi</i>	Felidae including <i>Panthera leo</i> , <i>Felis silvestris</i>	1.5–2	Africa
<i>B. (syn. Achromaticus) rodhaini</i> = <i>B. quadrigemina</i>	?	Mice	1.5–2	Europe

inside the erythrocytes. Since *B. microti* (at least some strains) has a similar development in lymphocytes, it will probably also transferred to the genus *Theileria* in the future with respect to molecular biological findings and that its very small genome differs considerably from those of other babesians and especially from those of the species with large merozoites (Table 1).

Life Cycle of Babesia Species

The life cycle of the different *Babesia* species runs according to the scheme given for *Babesia canis* (Fig. 1).

Diseases Due to Babesia Species

Babesia species are the agents of several important diseases of a broad spectrum of hosts:

1. Babesiosis of humans
2. Babesiosis of cattle and other ruminants
3. Babesiosis of dogs
4. Babesiosis (piroplasmosis) of horses and other equids
5. Babesiosis (piroplasmosis) of felids

Babesiosis of Humans (and Rodents)

Name

The genus name *Babesia* honors the Romanian pathologist Victor Babès (1854–1926). The species names have their origin in Greek, *mikros* = small and *otus* = ear, and Latin, *divergere* = dividing.

Geographic Distribution/Epidemiology

The number of clearly defined human cases of babesiosis is rather low and does not reach 2,000 published cases. However, the distribution shows that they are spread worldwide with a clear dominance in the USA and in Europe inclusive Russia.

Morphology/Life Cycle

The life cycle of the species that are involved in human infections (*Babesia microti* and *B. divergens*) is established between ticks (final hosts) and vertebrates (intermediate hosts) (Table 1, Fig. 1). *Babesia microti* has its main intermediate hosts in rodents, while *B. divergens* uses mainly cattle. In the USA also rare cases of human infections with *B. gibsoni* stage have been reported, but were not well documented. This species has dogs as main hosts. In ticks (see Table 1) the gamogony runs inside the intestine. The syngamy of gametes leads to motile zygotes (so-called kinetes), which enter the salivary gland

Babesia Species, Fig. 1 Life cycle of *Babesia canis* (for others, see Table 1). 1 Sporozoites in saliva of feeding tick. 2–5 Asexual reproduction in erythrocytes of vertebrate host (dog) by *binary fission*, producing merozoites (5) which enter other erythrocytes. When merozoites are ingested by a tick (5.1), they become digested inside the gut (5.2). 6 Some merozoites become ovoid gamonts. 7, 8 After ingestion into the tick's intestinal cells, the ovoid gamonts form protrusions and thus appear as *ray-bodies* (8). Fusion of two uninucleate ray-bodies (gametes). 10 Formation of a *zygote*. 11–14 Formation of a single *kinete* from a *zygote* inside the inner vacuole. The kinete leaves the intestinal cell and enters cells of various organs (including the eggs) of the vector ticks. 15–18 Formation of several kinetes (sporokinets). This process is repeated

(15–18) and also proceeds in eggs of ticks. The infection is thus transmitted to the next generation of ticks (i.e., *transovarial transmission*). 19–21 Some of the kinetes penetrate cells of the salivary glands, where a large multinuclear sporont (YS, ES) is formed (inside the hypertrophic host cells) finally giving rise to thousands of small sporozoites (SP), which are injected during the feeding act (i.e., *transstadial transmission*). CY cytomere (uninucleate), DE digested erythrocyte, DK developing kinete, E erythrocyte, ES enlarged sporont (forming sporozoites), GP growing parasite (polymorphic stage), HC nucleus of host cell, IV inner vacuole, N nucleus, NH nucleus of host cell, R raylike protrusion, SP sporozoite, T thornlike apical structure, YS young sporont. Schizo-, gamo-, sporogony are English terms

Babesia Species,**Fig. 2** *Babesia microti*:

Giemsa-stained smear preparation. Note that some parasites possess one nucleus, others possess two nuclei (prior to binary fission), and one erythrocyte shows a Maltese-cross stage (arrows)

**Babesia Species,****Fig. 3** Giemsa-stained smear preparation of red blood cells infected with stages of *B. divergens*. Note as main characteristic the position of dividing stages being situated immediately below the cell membrane of the red blood cell

cells and also the eggs of females, wherein they start asexual divisions (sporogony), which result in the production of sporozoites, that are transmitted to the next host during the bloodsucking of the tick at the surface of a vertebrate host including humans. The sporozoites are tiny cells of only 1 μm in length and look similar in both species (Fig. 2), while the stages in the erythrocytes are differing in size (measuring initially in *B. microti* only 1–1.5 μm). In *B. divergens* the blood stages have a size of 1.5–2.5 μm soon after having

entered erythrocytes (Figs. 2 and 3). Their position and appearance vary in human erythrocytes. The stages of *B. microti* form rather often tetrad stages (= Maltese-cross stages), which give rise simultaneously to four merozoites. In *B. divergens* the stages in binary fission are often situated just below the cell membrane of the infected erythrocyte (Figs. 2 and 3). The main features of the developmental stages of both species are shown in Fig. 1 and in the chapters on other *Babesia* species (see section “[Babesiosis of Cattle and](#)

Other Ruminants”) as well as in the review publication of Mehlhorn and Schein (1984).

Symptoms of Disease

Infections of humans were first detected in the year 1956 in Europe (see Gorenflot et al. 1991). In these cases which according to our present knowledge were due to *B. divergens*, the symptoms of disease had been extremely severe leading to death in more than 50 % of the infected persons. Most of the patients had been splenectomized or were struck by another immunosuppressive effect. Then it was found that another *Babesia* species (*B. microti*) may also induce in immunosuppressed persons a severe disease with similar symptoms as those of *B. divergens*. In addition many human *B. microti* cases were found (especially in the USA), where immunocompetent as well as immunocompromised persons had developed rather mild symptoms of disease, so that they remained undetected. This led to the fact that these parasites were later often transmitted by blood transfusion or during the perinatal period to other persons. **Acute cases** due to *B. microti* are rare, while they were predominant in *B. divergens* infections.

Acute symptoms: They start with sudden high fevers (40 °C), shivering, diarrheas, headache, muscle pain, dyspnea, hemoglobinuria, anemia, and exhaustion. During this period 20–80 % of the erythrocytes are infected and become destroyed (hemolysis) within 2–3 days, a fact which mostly leads to death of the infected person. In *B. microti* infections, which mostly remain at a chronic stage, symptoms are in general unspecific, showing slight exhaustion, muscle pain, slight fever, and weakness. However, in cases of stress these mild infections may reach a severe status.

Diagnosis

The diagnosis is mostly difficult, since patients often do not remember having been bitten by a tick. Thus, the most significant method is to investigate Giemsa-stained blood smears. In case of *B. microti* infections, some of the red blood cells will show typical division stages inside the cytoplasm: so-called Maltese-cross stages (Fig. 2). In

these cases the normal reproduction inside the erythrocytes by binary fission has changed to a simultaneous production of four merozoites. In the case of *B. divergens*, such Maltese-cross stages may also occur; however, the diagnosis can be based on the occurrence of dividing stages being located directly below the inner side of the erythrocytic membrane (Fig. 3). The parasitemia rate depends on the species. While in cases of *B. divergens* 20–80 % of the erythrocytes may be infected, *B. microti* infections show mostly less than 2 % of infected erythrocytes. Thus, in the latter case, the use of the thick droplet method is recommended. To differentiate *Babesia* infections of humans from those due to ► *Plasmodium* species (agents of malaria), the following criteria should be considered:

1. *Babesia* stages have often a pear-like body shape and are often seen during binary fission showing a V-like shape inside the erythrocyte.
2. In *Babesia* no schizonts occur inside erythrocytes (at the maximum four merozoites are formed at once = Maltese-cross stages) (Fig. 2).
3. Stages of *Babesia* do never contain pigment (= remnants of digested hemoglobin, while they are common in *Plasmodium* species).
4. *Babesia* stages are always situated directly inside the cytoplasm of the erythrocyte and never in a ► parasitophorous vacuole as it is the case in *Plasmodium* species.

In addition to the differentiation from *Plasmodium* species, *Babesia* species can also clearly be differentiated by the help of Giemsa-stained smear preparations from *Theileria* species, which also infect red blood cells. However, *Theileria* species had never been found in humans.

Infection

Babesia sporozoites are transmitted during the bloodsucking of infected ticks. However, in cases of human babesiosis, also infections occurred during blood transfusions or perinatally from mother to baby. Even iatrogenic transmissions (by contaminated syringes, etc.) are possible.

Prophylaxis

Repellents are sprayed on clothes and the skin to protect humans from tick bites. Avoid pressing of already attached ticks during removal, since otherwise sporozoites may be transmitted during pressure.

Incubation Period

One to four weeks.

Prepatent Period

One week.

Patency

Up to 1 year or even longer in chronic cases.

Treatment

There are several possibilities to treat *B. divergens* infections. Gorenflot et al. (1991) saved lives of several severely infected persons by the following treatment scheme:

1. Two to three times blood exchange of 1–1,5 l
2. I.v. application of clindamycin (3–4 × 600 mg per day)
3. Additional application of quinine (3 × 600 mg per day)
4. The chemotherapy should be repeated daily for 10–11 days

In more recent times the two following products have been used by several authors to treat both *Babesia* infections:

1. Adults (70 kg):

Quinine	650 mg	p.o.	3 × daily
Clindamycin	600 mg	p.o., i.v.	3 × daily
Azithromycin	(a) 500 mg	p.o., i.v.	1 × daily
	(b) 250 mg	p.o., i.v.	1 × daily (from day 2)

2)

Atovaquone	750 mg	p.o.	2 × daily
Doxycycline	200 mg	p.o.	1 × daily

In cases of immunosuppressed persons, higher dosages are needed.

2. Children:

Much lower dosages have to be given:

For example, quinine (8 mg), clindamycin (7–10 mg), azithromycin (5–10 mg), and atovaquone (20 mg).

These products had been given always in combinations:

- (a) Quinine + clindamycin
- (b) Atovaquone + azithromycin

Babesiosis of Cattle and Other Ruminants

Name

Victor Babès (Romanian pathologist; 1854–1926). Latin: *divergere* = dividing; *maior* = bigger; *bigeminus* = two times double; *bos*, *bovis* = cattle; *moto* = moving; *capreolus* = deer.

Geographic Distribution/Epidemiology

Worldwide – depending on the species (due to selling animals; local distribution: see Table 1). Some species may induce epidemics in herds in case the herd feeds in a region with high tick pressure.

Morphology/Life Cycle

The babesiosis of ruminants is introduced by transmission of the sporozoites of different *Babesia* species during bloodsucking of ixodid ticks (Table 1; Fig. 1). The sporozoites are mostly less than 1 µm long and are produced in the salivary glands of ticks after the gamogony had occurred in their intestine. The sporozoites as well as the blood-stage merozoites show in principle the same organelles as all coccidian except for the lack of the ► **conoid** and of the ► **micropore**. The different species produce mainly by binary fission intraerythrocytic merozoites (Figs. 3, 4, 5, 6, and 7), which are situated immediately inside the cytoplasm and which are set free by rupture of the host cell.

Cattle Harbor the Following Species

1. *Babesia divergens* merozoites (Fig. 3) have a size of up to 2 × 1 µm inside erythrocytes and are located extremely often immediately below

Babesia Species,

B

the host cell membrane. Inside the vectors are *Ixodes ricinus* and *I. persulcatus*, where they run gamogony inside the intestine and sporogony in the salivary glands and in the eggs. Thus practically all ticks are infected at certain epidemic spots.

2. *Babesia major* occurs in limited numbers in small endemic regions, where the vector tick *Haemaphysalis punctata* is found. The erythrocytic merozoites measure about $3.5 \times 1.5 \mu\text{m}$, are mostly situated centrally inside the red blood cell, and are pear shaped.
3. *Babesia bovis* is with respect to its wide distribution and its strong pathogenicity the most important *Babesia* species of cattle. It occurs in many regions together with *B. bigemina*. Both species are transmitted by ticks of the genus *Boophilus*, but also in some regions by species of the genera *Rhipicephalus* and *Ixodes*. The intraerythrocytic merozoites measure about $2.5 \times 1.5 \mu\text{m}$ (Fig. 5).
4. *Babesia bigemina* stages measure $4\text{--}5 \times 2\text{--}3 \mu\text{m}$ and thus belong to the largest *Babesia* species (Figs. 4 and 6). The merozoites are pear shaped; the stages before division often appear spherical-ovoid.

Sheep Harbor the Following Species

5. *Babesia motasi* is among sheep *Babesia* species the most important one, although it occurs only rarely (Fig. 7). The intraerythrocytic stages measure $4 \times 2 \mu\text{m}$. Vectors are – depending on the region – *Ixodes ricinus*,

Rhipicephalus bursa, *Dermacentor marginatus*, and *Haemaphysalis punctata*.

6. *Babesia ovis* merozoites appear mostly ovoid with a diameter of $1.5 \times 2.5 \mu\text{m}$. This species occurs in sheep in the countries of the Caucasus, in South Russia and in Ukraine, in countries of the Balcony, as well as in France and Spain. Furthermore, herds have been noted in Near East and in Far East in Central Asia, in Northwest and East Africa, as well as in South and Central America apparently due to worldwide sheep selling. Vectors are *Rhipicephalus* and *Hyalomma*.
7. *Babesia crassa* was detected in sheep in Iran as well as in goats. Its red blood stages measure $2.5 \times 2 \mu\text{m}$ and are nearly spherical. In this species the division inside the erythrocytes is a multiple one, giving rise always to more than four at each division. The vectors, however, have not yet been detected.

Wild Ruminants Harbor the Following Species

8. *Babesia capreoli* was first described in German deer, stags, and chamois, but could not transferred experimentally to cattle, goats, or sheep with respect to morphology and physiology; this species is similar to *B. divergens*. The vectors are not yet known.

Symptoms of Disease (Babesiosis)

In cases of infections with *B. bovis*, *B. bigemina*, *B. divergens*, and *B. ovis*, mainly adult animals

Babesia Species,

Fig. 8 Urine of uninfected animals (*left*) and *Babesia*-infected animals showing hematuria

showed intense pathogenic effects, which lead often to death. Some species (e.g., *B. ovis*, *B. bigemina*, *B. bovis*, *B. divergens*) may introduce mortality rates of up to 50 %. Leading symptom is bloody urine, since reproduction of the parasites inside the red blood cells leads to the destruction of the host cell (Fig. 8). The infection mostly starts with fever (40–42 °C), diarrhea, apathia, nonfeeding, paresis, and spasms. These symptoms are followed by anemia, icterus and often severe hemoglobinuria, erythropenia (only one to three million/mm³), and leukocytosis (up to 80 %).

Diagnosis

Giemsa-stained blood smears give very good and very early information, since the red blood cells contain already 7–10 days after an infection merozoites inside their cytoplasm, while clear hematuria occurs in general only several days later (Fig. 8). Serologic methods are mainly used to detect latent or older infections.

Infection

The vector ticks inject sporozoites within their saliva. This is done by all stages (larvae, nymphs,

♂♀), since they may become infected as well during bloodsucking as already in the uterus of the mother ticks, since in most *Babesia* species, transovarian transmission occurs.

Prophylaxis

Most useful: treatment of cattle with insecticides (dips, sprays). In some cases experimental infections and following treatment showed also good results.

Incubation Period

Variations according to the species, but mostly 8–10 days.

Prepatent Period

Seven to fourteen days (depending on the species and on the infection dosis).

Patency

Months up to years (depending on the various species of hosts and parasites).

Treatment

The treatment with diminazene aceturate (3.5–8 mg/kg bodyweight), which has to be deeply injected into muscles at several places, is

Babesia Species,

Fig. 9 Giemsa-stained smear preparation of red blood cells of a dog infected with *Babesia canis canis*

**Babesia Species,**

Fig. 10 Giemsa-stained smear preparation of red blood cells of a dog infected with *Babesia gibsoni* (Photo: Prof. Heydom)

very successful. The waiting time for milk is 3 days, that for meat 20 days. Furthermore, imidocarb is successfully used (1.2–3 mg/kg bodyweight) when subcutaneously injected. Waiting time for imidocarb is 90 days. In case of babesiosis of sheep, imidocarb was recommended to be used subcutaneously two times at an interval of 24 h in a dosis of 1–1.2 mg/kg bodyweight.

Babesiosis of Dogs

Name

Victor Babès (Romanian pathologist; 1854–1926) has described the infectious stage of a today *Babesia* species; Latin: *canis* = dog.

Geographic Distribution/Epidemiology

These *Babesia* species are worldwide distributed by transportation of dogs:

- *B. canis canis*: worldwide, Italy, Spain, Portugal, other Mediterranean regions, and North Africa (Fig. 9)
- *B. canis vogeli*: in tropics (between 35° south and 56° north)
- *B. canis rossii*: South Africa
- *B. gibsoni*: Europe, Asia, and North Africa (Fig. 10)
- *B. conradae*: California
- *B. annae* (syn. *Theileria annae*): Spain and Portugal

Babesia Species,

Fig. 11 Dog with anemia as a leading symptom for a *B. canis canis* infection

**Morphology/Life Cycle**

The life cycle of the *Babesia* species is diagrammatically depicted in Fig. 1 in the introduction of the chapter ► *Babesia*.

There are large pear-like species (*B. canis* complex), measuring 4–5 μm in length, and small ones (*B. gibsoni*, *B. annae*, *B. conradae*) with a size of about 1 μm in diameter (spherical shape). The transmission is strictly bound to specific tick species:

1. *B. canis canis*: *Dermacentor reticulatus*
2. *B. canis vogeli*: *Rhipicephalus sanguineus*
3. *B. canis rossi*: *Haemaphysalis leachi*
4. *B. gibsoni*: *Haemaphysalis* and *Rhipicephalus* species

Symptoms of Disease (Babesiosis)

Dogs can be infected at any age; however, severity or even mortality depends on the different strains and on the fitness of the infected animal respectively on the question whether the dog is freshly imported into an endemic region or not. 100 % mortality is reached by infections with *B. canis rossi*, while *B. canis canis* mostly produces only a parasitemia of 1 %, but may also kill the animal. *B. vogeli* is much less pathogenic and remains often symptomless in subclinical infections. *B. gibsoni* leads to severe infections. This type of infection (independent due to which species) starts with apathia, fever, weakness, loss of condition and weight, anemia (Fig. 11),

thrombocytopenia, icterus, hemoglobinuria (blackish urine, Fig. 8), edemas and bleedings along mucous layers, problems with breathing, and paresis. Death occurs as consequence of destruction of kidneys and/or enterorrhagic bleedings.

Diagnosis

Microscopical analysis of Giemsa-stained blood smears. IFAT, ELISA, and Dot-ELISA techniques and/or demonstration of specific cDNA by the help of PCR.

Infection

Bite of species-specific ticks (see Table 1).

Prophylaxis

Protect dogs by repellents and/or acaricides. In Europe there exist several vaccines against *B. canis* (Nobivac[®], Piro[®], Pirodog[®]); however, efficacy is not 100 %. Furthermore, a two-time prophylactic treatment is recommended using imidocarb subcutaneously (1 $\times$ 6 mg/kg bodyweight) 14 days and 4 weeks before departure into an endemic region. Protection is given for about 4 weeks after the last dosis. Use in addition repellents against attacking ticks. There are chemical repellents being active for 4–6 weeks and biological ones active for up to 3 days.

Incubation Period

One to three weeks.

Babesia Species,

Fig. 12 Comparing presentation of light micrographs of intraerythrocytic stages of *Babesia caballi* and *Theileria equi* (syn. *Babesia equi*). For *T. equi* typical Maltese-cross stages are characteristic

B

Prepatent Period

Three days in the case of *B. gibsoni* and 1–2 weeks in *B. canis*, depending on the strain.

Patency

In case of survival premunity occurs, and parasites remain present in low numbers, which can be seen in tests using the thick droplet technique.

Treatment

In many countries no drug is registered for treatment of dog babesiosis. However, internationally available is imidocarb at a dosis of 3.6 mg/kg bodyweight or diminazene aceturate at a dose of 1.17 mg/kg bodyweight to be given subcutaneously on three consecutive days for infection with *B. canis* strains. In case of *B. gibsoni* infections, parvaquone (20 mg/kg bodyweight, intramuscularly), phenamidine (15 mg/kg bodyweight, subcutaneously), or sulfadiazine plus trimethoprim (25 plus 5 mg/kg bodyweight, per oral) had been successfully used.

Babesiosis (Piroplasmosis) of Horses and Other Equids

Name

Babesia = honoring the discoverer of the genus (Victor Babès – 1854–1926). Latin: *caballus* = horse, *equus* = horse.

Geographic Distribution/Epidemiology

South Europe, South and Central America, Africa, Asia, Japan, often imported cases.

Morphology/Life Cycle

- (a) ***B. caballi***: The merozoites inside the red blood cells measure $2.5\text{--}4 \times 2 \mu\text{m}$ and appear pear shaped (Figs. 12 and 13). The life cycle runs like that of *B. canis* (see Fig. 1 in the introduction of ► *Babesia*).
- (b) ***Theileria* (syn. *B. equi*)**: The merozoites in the erythrocytes are tiny and reach a maximum length of $2 \mu\text{m}$ (Fig. 12) and often show division stage like a Maltese cross. The life cycle follows the phases established in the ► *Theileria* species, since prior to the reproduction, a schizogony occurred in the lymphocytes of the horse (Mehlhorn and Schein 1998). Furthermore, there occurs no infection of the eggs of the tick in the ovary as it is the case in typical *Babesia* species.

Symptoms of Disease

T. equi is much more pathogenic than *B. caballi*, since infections reach a parasitemia of 80 % (mean 20 %) compared to only 2–10 % in *T. equi*. However, both infections introduce severe symptoms in adult animals, while younger animals suffer much less. Severe infections lead to high fever (42°C), apathia, hemorrhages, hemolytic anemia, icterus, splenomegaly, clumping of erythrocytes

Babesia Species,

Fig. 13 Giemsa-stained blood smear showing clumping of *B. caballi*-infected red blood cells (Photo: Prof. Heydom)

(Fig. 13), and liver swellings. While hemoglobinuria is common in infections (seen as nearly black urine, Fig. 8), it occurs rarely in *B. caballi* infections. Peracute infections may lead to death in a few days. After survival most a so-called premunity is obtained which protects for some months. Chronic infections in *B. caballi*-infected animals may last months up to 4 years introducing loss of weight, weakness, and pareses of the back legs.

Diagnosis

Giemsa-stained blood smear shows the typical merozoites inside the erythrocytes (Figs. 12 and 13). Serological investigations are needed (KBR, IFAT, ELISA, SELISA, etc.) before horses may become imported into several countries (e.g., the USA, Australia).

Infection

During tick bites sporozoites are injected within saliva, since they are formed inside the salivary glands. Vectors are *B. caballi*, species of the genera *Dermacentor*, *Anocentor*, and *Hyalomma*, and *T. equi*, *Hyalomma* sp., *Rhipicephalus* sp., and *Dermacentor* sp.

Prophylaxis

Use of repellents (e.g., Viticks® for horses, Fa. Alpha-Biocare, Düsseldorf), which protect for 3 days during staying on pasture, or use of chemical contact insecticides.

Incubation Period

Two to ten days.

Prepatent Period

Two to seven days.

Patency

Eventually years (in *B. caballi*).

Treatment

Clinical healing of a *B. caballi* infection may be achieved by intramuscular injection of 3.5 mg/kg bodyweight diminazene on two consecutive days. Elimination of any parasite would need doubling the dosis. *T. equi* considerably resists the treatment. However, the intramuscular injection of 4×5 mg/kg bodyweight imidocarb at intervals of 3 days leads to clinical healing, while in 50 % of the cases, the parasitic stages are not completely eliminated. **Important:** the dosis should be divided and injected at several places.

Babesiosis (Piroplasmosis) of Felids

In felids a series of *Babesia* species are described: *B. cati* (in India), *B. felis* in house cats (region of the Mediterranean Sea, India, the USA, and South Africa in lions and leopards), and *B. herpailuri* (syn. *B. pantherae*) in South America in Jaguarundis and in Africa in leopards and house cats. Their life cycles are scarcely investigated. All erythrocytic stages are rather small and range between 1.5 and 2.5 μm in length (Figs. 14 and

Babesia Species,

Fig. 14 Light micrograph of a smear preparation of red blood cells with *B. pantherae* (Photo: Prof. Heydorn)

B

Babesia Species,

Fig. 15 Light micrograph of a smear preparation of red blood cells with *B. felis* (Photo: Prof. Heydorn)

15). Their life cycle is unknown in many. For *B. equi* ticks of the genus ► *Haemaphysalis* act as vectors. As in other babesiosis, the main **symptoms of disease** are anemia, icterus, and general weakness until death. Treatment can be done using primaquine phosphate (0.5 mg/kg bodyweight) given orally or per intramuscular injection.

In North America another agent of a piroplasmosis (natural host: bobcat, *Lynx rufus*) had been described as *Cytauxzoon felis*, which develops 2 µm long intraerythrocytic merozoites. However, this species has also a lymphatic development of cats. Thus, it is probably also a ► *Theileria* species as *B. equi*. The vector is the tick species *Dermacentor variabilis*. About 2 weeks after the tick bite, cats suffer from swelling of the lymph nodes, fever, and icterus, and in most cases they die. A successful therapy is not

known. Diminazene treatment did not clear parasitemia – a fact, which supports the idea that it is a *Theileria* species.

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Economic Importance

Members of the genus ► *Babesia* occur throughout the world and may cause a wide range of clinical syndromes in most domestic animals and humans due to differences in virulence within each *Babesia* species. They are transmitted by hard ► ticks (► *Ixodidae*) during blood meals and may produce diseases in their hosts, which are characterized by an acute febrile reaction, jaundice, hemolytic anemia, hemoglobinuria, and variable mortality. The babesiosis is of major economic importance in cattle because the majority of about 1.2 billion cattle in the world are potentially exposed to *Babesia* spp. because of the extensive husbandry methods employed in raising these animals. *Babesia* spp. infections may also occur by the frequent introduction of *Babesia*-free animals into *Babesia*-enzootic areas and by introduction of tick vectors and *Babesia* spp. into clean zones. The greatest economic loss is due to *Babesia* spp. infections in cattle, particularly in the USA, Australia (State of Queensland), South Africa, and South America. Indigenous animals are normally protected from babesiosis in early life by premunition resulting from continuous reinfection. In regions with enzootic stability, babesiosis is not a disease problem, and control measures are not necessary. In these zones, calves are still protected by maternal antibodies which they had received through the colostrum. Subsequently, the animals remain carriers by repeated natural infections.

Epizootiology and Enzootic Stability of Bovine Babesiosis

The idea of maintaining enzootic stability is to allow limited challenge of the parasite and the

tick to cattle without producing disease or loss of production. The immune status of a herd can be monitored serologically, and in cases where more than 50 % of cattle show no antibabesial serum titers, the whole herd should be vaccinated. Thus, the efficient application of vaccination procedures depends considerably on the ► [epizootiology](#) of babesiosis and involves knowledge of the complex interaction of the host, *Babesia* parasite, and vector. The aim of premunization (see section “[Premunization and Use of Antibabesial Drugs \(Chemoimmunization\)](#)”) or immunization with live blood-derived vaccines of attenuated strains of *B. bovis* and *B. bigemina* is to maintain herd immunity and thus the balance between host and vector. In various countries, the idea of reestablishing areas of enzootic stability has strongly been supported, particularly after the introduction of “tick-resistant” cattle and the occurrence of increasing failures of chemical control measures.

Strategic Tick Control in Areas with Enzootic Instability of Babesiosis

Attempts at controlling babesiosis in districts with enzootic instability (i.e., where less than 90 % of cattle show premunition) can be directed against the tick vector (for more details see control of ► [ticks](#), and application techniques). There are one-host ticks (e.g., ► [Boophilus](#) spp.), two-host ticks, and three-host ticks (e.g., ► [Rhhipicephalus](#) spp., ► [Haemaphysalis](#) spp.; *Ixodes ricinus*) which can be controlled by aggressive or strategic dipping (this latter method may involve three dippings in the dry season and is used, e.g., in Australia) plus pasture improvement and/or pasture spelling at intervals of 8–10 weeks in summer or early autumn. Aggressive dipping is still imperative in areas where, in addition to babesiosis, East Coast fever, heart water due to *Cowdria ruminantium* infection, and ► [anaplasmosis](#) (*Anaplasma centrale* and *A. marginale*) occur. This method involves acaricide administration at regular intervals, either throughout the year or during tick seasons, with the aim of eliminating the tick vector. The application of acaricide can be

done in any of three ways. These may be (1) a plunge bath, communal dip, or dip on large farms; (2) a spray-race (system of pipes fitted with spraying nozzles) on large farms; or (3) a hand-spraying system consisting of a large water container and a hand pump or small motor pump. The strategic dipping system, i.e., administration of an acaricide at certain time intervals, may lead to temporarily unstable situations since transmission of *Babesia* spp. and *Anaplasma* spp. is not completely interrupted; in this case an additional vaccination against both organisms is advisable.

Tick Control in Livestock to Prevent Babesiosis

Today, the only conventional control measure against argasid and ixodid ticks is the use of acaricides for animals at risk. Pesticides belong to different chemical groups such as chlorinated hydrocarbons, organophosphates, carbamates, diamidines, synthetic pyrethroids, and avermectins. Drugs of these groups have different mode and site of actions. For instance the growth regulator **fluazuron** inhibits the ► [chitin](#) formation in ticks. Its effect results in reduced production of viable eggs in engorged females and may reduce pasture contamination.

Acaricidal control of vectors to protect animals from disease has been applied in many countries although with only limited success, as ticks rapidly developed resistance to pesticides and acaricides (ectoparasitocidal drugs, ► [arthropodicidal drugs](#)). However, acaricide treatment continues to be necessary although drug tolerance of ticks to most agents, except the macrocyclic lactones, is common. In the field, there may occur tremendous economic losses due to breakdown of dipping systems in various regions, the increasing cost of acaricides often beyond the means of many farmers, and the lack of veterinary infrastructure in many countries that have made the eradication of tick vectors impossible.

Closantel used for the control of helminthic infections (nematocidal drugs, animals, trematodocidal drugs) of sheep and cattle and

larval stages of nasal botfly (► *Oestrus ovis*) of sheep has been shown to have a marked effect also on ► **fecundity** and egg viability of ticks. The strongly plasma-bound drug is ingested by ticks while feeding and probably affects their mitochondrial energy production by inhibiting oxidative phosphorylation and thereby adenosine triphosphate synthesis. Thus, closantel may play a role in tick control strategies, due to its effect on tick reproductive cycle being greatest at time of dosing. Current alternative control measures and their effective use in the field are still of minor importance. ► **Biological control** of ticks with living antagonists distributed by man to lower pest (parasite) populations may lead to their reduction and so to acceptable subclinical densities. In the field, however, the use of biological agents as formulations (products) of viruses, bacteria, fungus, protozoans (e.g., ► **microsporidia**), ► **nematodes**, and insects, or pheromones, are very much limited and less promising in their effects today. A more successful control measure against widely distributed *Boophilus* spp. and other tick species seems to be the immunization of cattle with recently developed antitick vaccines. The antigens of interest against ticks are native or recombinant proteins located in the gut cells' plasmatic membrane. They are called "novel, concealed, or occult antigens" causing lesions in the tick's intestine, thereby reducing the fecundity of ticks. Other putative antigens seem to be located in cells of the salivary glands preventing feeding of the ticks and thus depressing their fertility.

Control of Babesiosis by Various Application Techniques of Acaricides

Acaricides can be applied to animals by different application techniques. When treating animals for external parasites, it is important that agents not absorbed through the skin, or from the digestive tract, or parenteral injection be so applied that contact with the parasite will occur. Dips and sprays generally are suited for treating most animals (especially herds) except when temperatures are below freezing or extremely thirsty animals

are to be treated. Systemic drugs, usually the organophosphates and macrocyclic lactones (ivermectin, moxidectin, doramectin, and eprinomectin), are applied as pour-ons, spot-ons, injectables, sprays, and feed additives, or via dipping vats (tanks). These agents gain access to the host circulatory system and are then distributed throughout the body. **Dipping** probably offers the best means and most cost-effective method of tick control for cattle in tropical areas and for dogs (is less frequently used for cats). Dipping with acaricides has the advantage of thorough coverage of the skin, coat, and head of cattle (if deep tanks are used). When using such agents, caution must be exercised to prevent contaminating humans and their food supply and environment.

Premunization and Use of Antibabesial Drugs (Chemoimmunization)

Bovines of an enzootic area commonly acquire a so-called infection-immunity or **premunition** against babesiosis in the first six months of life. As a result, most of the cattle of enzootic areas are carriers of a few parasites and will therefore develop a certain degree of protective immunity against local *Babesia* strains without showing signs of disease. In contrast, elimination of the infection by curative agents is soon followed by loss of resistance to the parasite in most hosts. Cattle introduced from areas free of *Babesia* or with parasites of different antigenic strains may acquire babesiosis and die. **Premunization** (artificial induction of premunition) has allowed the introduction of quality cattle into enzootic areas of Australia, the USA, Latin America, and elsewhere. Animals introduced are injected with blood from *Babesia* carriers and monitored for the presence of fever and parasitemia. Soon after clinical signs are apparent, animals are treated with subcurative doses of diminazene aceturate or imidocarb dipropionate (Table 1), thereby killing enough parasites to prevent an outbreak of disease but allowing some surviving parasites to induce protective immunity to natural challenges in hosts. Animals can be injected simultaneously with a standardized dose (several million

Babesiocidal Drugs, Table 1 Babesiocidal drugs used in domestic animals

Chemical group (approx. dose, mg/kg b.w., route, animal)	Nonproprietary name, *brand name (company, manufacturer)	Characteristics and miscellaneous comments
AZO-Naphthalene Dyes		
(cattle, 2–3, i.v.; dog, 10, 1 % solution, i.v.) ^a 1909	Trypan blue (syn. Congo blue, Niagara blue) *Trypan Blue SS (Centaur Lab., S. Africa): discontinued	First specific drug with activity against <i>B. bigemina</i> and other large species; i.v. application leads to blue staining of meat, body secretions, and milk (today, largely replaced by diamidines); discoloration of mucous membranes and plasma interferes with clinical and laboratory parameters; there are severe local reactions after extravascular injection; drug can be used in treating <i>B. canis</i> infection in dog but relapse may occur; diminazene may sterilize infection
Acridine derivatives		
(Cattle, 4.4 ml/100 kg, 5 % solution, i.v.) ^a 1919	*Acriflavine HCl *Euflavine HCl *Gonacrine HCl (Merial, others) (no longer in use as antibabesial drugs)	Is active against <i>B. bigemina</i> and other large <i>Babesia</i> spp.; like trypan blue, it proves less effective against <i>B. bovis</i> ; i.v. administration limits its use under field conditions; drug is relatively well tolerated at recommended dose; discoloration of tissues is less pronounced than that caused by trypan blue
Urea derivatives (quinolone derivative) (cattle, 1–2 ml/100 kg, 5 % Acaprin solution, 1–2 injections, 24 h interval, s.c; dogs, 0.25 ml/5 kg, 0.5 % Acaprin solution, s.c.) ^a 1935	Quinuronium sulfate *Acaprin (Bayer) *Ludobal (Bayer) *Babesan *Akiron, Pirevan, Piroplasmin, and others (various manufacturers in India and China)	For many years, the drug of choice in treating bovine babesiosis (<i>B. bigemina</i> , <i>B. bovis</i> , <i>B. divergens</i>); it is active against large <i>Babesia</i> spp. of swine, horse, and dog; drug has a low therapeutic index and may stimulate parasympathetic nervous system (excessive salivation, frequent urination, or dyspnea caused by anticholinesterase activity; antidotes are atropine or epinephrine; in fatal cases volvulus of jejunum has been observed, which may result from hyperperistalsis); its mode of action is uncertain; action of drug on <i>B. felis</i> see text
Diamidines		
Carbanilides (cattle, 5–10, i.m.; horses 8, i.m.) ^a 1964	Amicarbalide diisethionate *Diampron (Merial)	Is effective against <i>B. bigemina</i> , <i>B. caballi</i> , and <i>B. motasi</i> but there are differences in efficacy against large <i>Babesia</i> spp.; its effect on small <i>Babesia</i> spp. is less pronounced (clinical remission only)
(Cattle, 1.2–2.4, s.c; horse, 2–2.4, i. m.; 2 injections, 24 h interval; dog 5–6, i.m. 1–2 injections, 24 h interval) ^a 1969	Imidocarb dipropionate *Imizol, *Carbesia (Schering-Plough AH) *Forray-65 (Bayer, SA)	Is effective in preventing and treating bovine babesiosis without interfering with development of immunity; protection period may last for several weeks depending on dose used; drug

Chemical group (approx. dose, mg/kg b.w., route, animal)	Nonproprietary name, *brand name (company, manufacturer)	Characteristics and miscellaneous comments
		shows efficacy against <i>B. canis</i> infections and equine babesiosis. Fine-structural alterations of <i>B. herpailuri</i> in cats treated with the drug were less pronounced and resulted in widening of subpellicular endoplasmic reticulum and perinuclear; drug is very slowly eliminated; bile is an important route of excretion; there is a long preslaughter withdrawal period (cattle; sheep) for edible tissues and milk of approx. 90 days and 21 days, respectively; data on toxicity are somewhat erratic; there is a wide range of individual animal tolerance to the drug; side effects are due to anticholinesterase activity, and fatal toxicosis is usually associated with renal disorder (necrosis), edema, hydrothorax, hydroperitoneum, and pulmonary congestion; mortality in equines (which can occur at 4 mg/kg or higher doses) is attributed to acute tubular renal necrosis; mechanism of drug action is known (possibly interferes with nucleic acid synthesis, see diminazene ↓); excess of polyamines (e.g., spermidine) can nullify trypanocidal activity of imidocarb and amicarbalide; the diamidine imidocarb also proved active against <i>Trypanosoma brucei</i> mouse infection and <i>Anaplasma marginale</i> infection in cattle at 3 mg/kg b.w (elimination of parasites is not achieved).
Aromatic diamidines		
(Dog, 5–10, i.m., 15, s.c. 1–2 injections, 24 h (48 h: s.c.) interval; horse, 8, i.m., 1–2 injections, 24 h interval) ^a 1939	Phenamidine diisethionate *Lomidine (Merial) *Oxopirvedine (Merieux) *Phenamidine (Virbac, SA)	Is used mainly in treating canine and equine babesiosis; it has also been used successfully in <i>B. bigemina</i> infections; frequent relapses may occur in <i>B. gibsoni</i> infections in dogs; drug can be used for eradicating carrier infections in horses; side effects of drug are similar to those noticed with pentamidine; it is well tolerated at recommended dose although s.c. injections may lead to moderate swelling (necrosis, mainly in horses); drug may cause transient immunosuppression in dogs; mechanism of drug action is uncertain but may be similar to that of

(continued)

Data given in the table have no claim to full information
^aFirst practical (commercial) application (approx. year)

organisms of each species per animal) of *B. bigemina*, *B. bovis*, and *Anaplasma marginale* (*Rickettsia* species) derived from blood of donor bovines often splenectomized. They are then treated well timed with imidocarb or with long-acting tetracyclines, which are active against both *Babesia* and *Anaplasma*. Premunization has several drawbacks. The main obstacles, like the occurrence of hemolytic disease in newborn calves (antibodies against erythrocyteisoantigens), transmission of other blood-borne pathogens (e.g., leukosis virus), or storage and transportation problems of the “vaccines,” have largely been overcome but some problems remain. Thus premunization prevents eradication of the parasites, may cause economic losses (outbreak of disease or occurrence of mortality in herds), may induce a variable resistance status in cattle, and is expensive. On the other hand, there may be some advantages concerning premunization. Thus, its application is still needed in large enzootic areas because refinements to the system of immunization with attenuated parasites are not yet satisfactory with regard to tolerability of vaccines. Occasionally, there are adverse effects such as ► [abortion](#), hemolytic neonatal disease, or induction of severe babesiosis. The safety of blood-derived vaccines is not always guaranteed, and transmission of other hematogenous infections cannot be absolutely excluded. This may also be true for the stability of vaccines.

They may fail to induce strong herd immunity because of instability of vaccinal parasites or changes in selection of field strains, or prolongation of vaccine shelf life beyond expiration date. Intolerability of vaccines may be shock and disturbances of the blood-clotting mechanisms and calcium balance.

Chemotherapy of Babesiosis in Animals

The elimination of *Babesia* (Table 1) in cattle or horses may play an important role for those animals which have a low-grade infection premunition. In these cases, it must be guaranteed that carrier animals are free from infection before being imported into *Babesia*-free areas. However, when drugs are used therapeutically in endemic regions, the aim is to promote clinical recovery only and to allow some parasites to survive, reestablishing premunition. Thus, instead of the chemoimmunization programs (see Premunization and Use of Antibabesial Drugs) that are used in districts with enzootic stability or instability, in countries where *Babesia* are rare, the so-called diagnosis-treatment method is employed. There are several drugs in use, all of which are “old-timers” and are more or less afflicted with adverse effects involving long withdrawal periods for meat and other edible tissues. Drugs commonly used in treating acute ovine or

porcine babesiosis are quinuronium sulfate, imidocarb, and diminazene, which have sufficient efficacy against clinical attacks. Infections with *Babesia* spp. in sheep, goat, and swine must be treated with somewhat higher doses than those normally recommended in cattle. Repeated administration of drugs may be necessary to cure *B. ovis* infections (for details regarding activity and toxicity of antibabesial drugs, see Table 1, ► [Trypanocidal Drugs, Animals](#); for pharmacokinetics of diminazene diacetate and ethidium bromide, see ► [Trypanocidal Drugs, Animals/Pharmacokinetics of Trypanocides and Chemical Residues in Edible Tissues and Milk](#)). The effect of an antibabesial drug may vary and can be modified by the severity of the disease, the dosage used, the timing of treatment in the course of infection, and the length of time that the drug is present to affect the parasite. As a rule, large *Babesia* spp. are distinctly more susceptible to chemotherapeutic agents than are the small ones. In general, small *Babesia* respond variably to antibabesial drugs. **Sterilization of infection**, i.e., complete elimination of parasites, is usually not achieved with small *Babesia* spp. possibly due to adherence of parasites to capillary walls and consequent obstruction of blood flow. There may be differences in relation and metabolism between small and large *Babesia* spp., and as a result the target and biochemical mode of action of drugs differ. Recovery of ill animals can be achieved if specific and effective treatment is given prior to the onset of severe anemia or disorders of the nervous system, i.e., in the early course of infection. Prognosis is poor for those animals already showing cerebral signs; these are caused by clumps of parasitized erythrocytes blocking capillary blood vessels of cerebral cortex. In severe cases the aim of supportive treatment (e.g., blood transfusion, fluid therapy) is to reduce the occurrence of shock and disturbances of the blood-clotting mechanisms and calcium balance.

Elimination of *Babesia* in Horses

Equine babesiasis is widespread; severe clinical disease and mortality may occur occasionally.

Therefore, the elimination of carrier infection in horses being shipped from endemic zones to *Babesia*-free areas gains increasing importance. Various drugs may be used for clearing *Babesia caballi* infections. Amicarbalide (8.8 mg/kg b.w., $\times 2$, 24 h interval), imidocarb (1–2 mg/kg b.w., $\times 2$, 24 h interval), diminazene (5 mg/kg b.w., $\times 2$, 24 h interval), and phenamidine (8.8 mg/kg b.w., $\times 2$, 24 h interval) may show sufficient action. *B. equi* (small species) has recently been transferred to the genus ► [Theileria](#) (see also Table 1: parvaquone).

Elimination of *Babesia* in Dogs and Cats

Canine babesiosis is becoming increasingly widespread in the USA, Europe, Africa (*B. canis*), and Asia (*B. gibsoni*). The disease can be treated with a few antibabesial drugs causing more or less toxic side effects, such as diminazene (which is not recommended for use in dogs by the manufacturer, Table 1), imidocarb, amicarbalide, phenamidine, and trypan blue. *B. canis* may cause uncomplicated infections (fever, depression, acute hemolysis with a mild to severe anemia, pale mucous membranes, and splenomegaly) or complicated ones (coagulopathy, hepatopathy, immune-mediated hemolytic anemia, renal failure, cerebral signs, pulmonary ► [edema](#), and shock). The specific therapy (if started too late, or in case of complicated infection per se) must be combined with supportive treatment (fluid infusion followed by blood transfusion, liver protectants, diuretics, vitamin B complexes, prednisolone). In general, drugs are distinctly less active against *B. gibsoni* than against *B. canis*. Relapses in *B. gibsoni* infections are common and may also occur after administering markedly higher doses than those recommended. Thus, diminazene in doses of 7–10 mg/kg b.w. only suppresses parasitemia, but these doses and even lower ones may cause severe side effects and occasionally mortality in dogs (Raether unpublished). *B. felis* infection, which may cause anemia and icterus in the domestic cat, has been reported to respond to trypan blue and quinuronium. These results are inconsistent with

those of Potgieter who found that all known antibabesial drugs failed to affect *B. felis*; successful treatment was achieved in using primaquine diphosphate. Concerning differential diagnosis of feline babesiosis, ► *Cytauxzoon felis* infection (*Theileria* species) should be considered; it may occur in North America and parasitize lymphocytes and erythrocytes of cats.

Chemoprophylaxis of Babesiosis in Animals

The aim of ► *chemoprophylaxis* is to protect susceptible animals from clinical signs of babesiosis caused by natural tick infection, or to moderate the clinical course of infection in immunization programs (see Premunization and Use of Babesiocidal Drugs). The administration of drugs like **diminazene**, **imidocarb**, or **oxytetracycline** (Table 1) should allow the development of premunition. Imidocarb, which exhibits a fairly long effect on *Babesia* spp. in cattle (4–12 weeks at 2 mg/kg b.w., depending on *Babesia* species and infection pressure), can also be used for short-term protection of susceptible animals after their introduction into *Babesia*-infected areas.

A single subcutaneous dose of 2.4 mg/kg b.w. **imidocarb** may protect dogs from *B. canis* infections for about 4 weeks. However, controversy exists concerning the duration of its prophylactic efficacy. So in Beagle dogs experimentally infected with *B. canis* (merozoites), a single dose of 6 mg/kg b.w. resulted in a 2-week protection period only. In enzootic *Babesia* areas, dogs can also be protected by long-acting acaricides applied in 4-day intervals or by application of inactivated vaccines (e.g., Pirodog®). Although these vaccines allow *Babesia* infections under high infection pressure, they may prevent infected dogs from mortality.

Resistance

Although ► *malaria* and babesiosis have many similarities, and their causative agents are related,

resistance of *Babesia* and malaria parasites to drugs differs markedly. While resistance of *P. falciparum* to drugs has probably become the most important threat to effective ► *control of malaria*, drug resistance in large *Babesia* spp. seems to be a minor problem in the chemotherapy of babesiosis. Resistance to babesiocidal drugs can be induced experimentally. Thus, in vitro microtiter tests (96-well flat-bottom plates) may be used to assess drug responsiveness of *B. bovis* or *B. bigemina* to various antibabesial compounds, thereby selecting drug-adapted lines by the presence of subinhibitory drug concentrations. Under field conditions, drug resistance in *Babesia* spp. may emerge if drugs are used prophylactically or in chemoprophylaxis programs. Using such dose regimes, it is likely that subtherapeutic, low concentrations of the drug are in temporary or permanent contact with the parasites, thereby causing selection of drug-resistant organisms. However, it must be emphasized that the innate poor response of small *Babesia* spp. (e.g., *B. bovis*, *B. ovis*, *B. gibsoni*, *B. felis*, *B. microti*) to antibabesial drugs should be distinguished from an acquired drug resistance occasionally occurring in large *Babesia*. Compared to the greater drug sensitivity of large *Babesia* spp., the varied action of drugs against small forms (“► *natural resistance*”) may well be connected with differences in their relation. Small species undergoing ► *schizogony* in lymphocytes (e.g., *B. microti*) appear in their fine structure very similar to *Theileria* spp. Molecular analyses of the small subunit ribosomal RNA genes (rDNA) suggest that small *Babesia* spp. may have a close relation to *Theileria* spp. There were a number of reasons why *B. equi* was transferred to the genus *Theileria*.

Chemotherapy of Human Babesiosis

Since the first description of human babesiosis in 1957 in a splenectomized patient in Yugoslavia, there have been several case reports from the USA, Europe, and other countries on babesiosis in man. The acquisition of human babesiosis may

depend on contact with subadult stages of certain *Ixodes* ticks, e.g., *I. dammini* (its main host is white-footed mouse, *Peromyscus leucopus*), and *I. ricinus* possibly transmitting *Babesia microti* (a rodent piroplasm) and *B. divergens* (a parasite of cattle), respectively. *B. gibsoni* is a parasite of dogs, and WA-1, a *B. gibsoni*-like piroplasm has been documented in residents along the Pacific Coast of the USA and may infect humans in Taiwan and South Africa too. The host (vector/tick) of WA-1 and its reservoir are still unknown. Although closely related to *B. gibsoni*, WA-1 should not infect dogs. However, it is highly pathogenic for most rodents. In humans, WA-1 and *B. microti* may cause a similar course of infection and symptoms. Apparent **clinical signs** are parasitemia (intraerythrocytic parasites show characteristic tetrad forms), fever, rigors, cough, headache, vomiting, anorexia, and dark-colored urine. Spleen-intact humans infected with *B. microti* or WA-1 may well respond to a combination of **clindamycin** (macrolide antibiotic) and **quinine** (*cinchona* alkaloid, Table 1, ► **Malariacidal Drugs/Malaria of Human**) although quinine proved to be totally ineffective against *B. microti*. In many areas of Europe, the enzootic cycle of *B. microti* may obviously depend on uniquely mouse-specific tick, *I. trianguliceps*. Possibly for that reason, this species is not transmitted to humans, or its European strains are not pathogenic to humans. Reported cases of human babesiosis in Europe are due to *B. divergens* and chiefly occur in farmers and other persons frequently in contact with cattle. As a rule, *B. divergens* infections in man show rapid increasing parasitemia and damage of large numbers of infected red cells causing massive hemoglobinuria, intravascular hemolysis, and renal failure. Therefore, an early start of specific treatment is important for any patients infected with *B. divergens*. The treatment of choice seems to be the immediate administration of clindamycin (adult dosage, 1.2 g, 2×/d IV or 600 mg, 3×/d PO × 7d) plus quinine (650 mg, 3×/d PO × 7d; all doses cited are from Medical Letter, 2004; pediatric dosage for both drugs see there). Chemotherapy is followed by a massive exchange transfusion to reduce parasitemia, i.e., to remove

physically large numbers of infected red cells and prevent extensive hemolysis and renal failure. Exchange transfusion may be used as an alternative or in addition to chemotherapy relying on relatively toxic drugs. However, this therapy with its attendant risks should be reserved for heavily parasitized and seriously ill patients only. Symptomatic and other supportive care should be associated with specific treatment. Clindamycin plus quinine treatment proved to be insufficient in immunosuppressed patients or in HIV infected ones. Therefore, in foudroyant infection courses, massive blood exchange may be lifesaving or application of **atovaquone** plus **azithromycin** (Medical Letter 2004) as was recently shown.

Pentamidine isethionate (a trypanocide, see ► **Trypanocidal Drugs, Man**) has shown good activity against *B. microti* but failed to eliminate parasites from blood completely. **Diminazene aceturate** (Table 1 and ► **Trypanocidal Drugs, Animals**), an aromatic diamidine like pentamidine and approved for use in animals only, has also been tested in humans. The drug was successful in treating a *B. microti* infection, which did not respond to therapy with oral chloroquine phosphate. The infection was eliminated, but the patient developed acute idiopathic polyneuritis, probably related to the diminazene therapy.

Babesians

Members of ► *Babesia* species, ► **Tick Bites: Effects in Animals**.

Babesiosis, Animals

Synonyms

Cardiovascular system diseases; Meadow red; Piroplasmosis; Redwater disease; Texas fever

General Information

Babesiosis is caused by infection with species of tickborne, intraerythrocytic and generally host-specific protozoan parasites of the genus ► *Babesia*. It occurs in a wide variety of vertebrate hosts and has a very wide distribution around the world. The two major factors involved in the pathogenesis of babesiosis are the release of pharmacologically active agents and intravascular haemolysis. The relative importance of each varies with the species of ► *Babesia*, e.g., the pathogenesis of *B. bigemina* is almost entirely related to haemolysis while with *B. bovis* the release of proteolytic enzymes which directly or indirectly affect the microcirculation and the viscosity of blood is the most important. Effects on the microcirculation include vasodilatation and increased vascular permeability, leading to hypotension and ► *oedema*. Higher viscosity and coagulability of blood and increased stickiness of the membrane of blood cells cause aggregation of cells in capillaries and obstruction of the blood flow. This may lead to congestion and degenerative changes in the spleen, lymph nodes, kidneys and brain. Whatever the species involved, the disease may follow acute, subacute or chronic courses, and there may be great variation in the clinical manifestations of infection.

Pathology

Cattle

Various species of *Babesia* (*B. bovis*, *B. bigemina*, *B. divergens* and *B. yakimovi*) are transmitted by ► *ticks* into wild and domesticated cattle. Large numbers of ruminants are killed by this parasite in tropical and subtropical areas of Australia, South America, Southern USA, and Africa where the parasites are endemic. The fight against babesiosis is a major economic factor in these areas. *B. bovis* infection is probably the most important cause of “tick fevers” of cattle. The fact that some breeds of *Bos indicus* are relatively resistant to the effects of this parasite has led to the suggestion that the organism evolved in these breeds. Young cattle

have pronounced resistance to severe infection. The first clinical signs are fever ($>40^{\circ}\text{C}$), loss of appetite and listlessness. ► *Anaemia* and ► *haemoglobinuria* (► *Redwater*) follow, and signs of jaundice develop. Diarrhoea is common and pregnant cows may abort. A form of “cerebral babesiosis” develops in some animals with such clinical signs as hyperaesthesia, nystagmus, grinding of teeth, circling, head pressing, mania, ataxia and convulsion. In terminal cases muscle tremors and wasting may appear, followed by coma and death. At post-mortem examination the blood appears to be thin and watery, and there is haemoglobinuria. All connective and fat tissues are oedematous and show evidence of icterus. The spleen is characteristically enlarged. The liver is swollen and the gallbladder distended. In cases of cerebral babesiosis the grey matter of the brain is congested and shows a typical red discolouration. Infection with *B. bigemina* causes similar but usually less severe clinical signs than infections with *B. bovis*, though acute anaemia and death also occur. The pathogenesis is here almost entirely related to a rapid haemolysis, with signs of haemoglobinuria and jaundice. There is no cerebral involvement. *B. divergens* and *B. major* are considered less pathogenic than other species in the tropics. In temperate regions, *B. divergens* causes the most severe signs and may be responsible for heavy economical losses. Clinical signs include fever, anaemia, ► *bilirubinuria* and haemoglobinuria. Diarrhoea, icterus, nervous signs and ► *abortion* may also occur in severe cases.

Horses

The horse parasite *Babesia equi* has recently been redescribed as *Theileria equi*. The only *Babesia* spp. which occurs in horses is *B. caballi*. The pathogenesis and clinical signs of infection are similar to those described above for other *Babesia* spp., i.e., that of an haemolytic anaemia which is compounded by phagocytosis of erythrocytes by macrophages. However, most infected animals are not clinically affected. Equine babesiosis is an important reason for the restriction of movements of horses between some countries.

Dogs

Babesia canis infection is a common cause of death in dogs. The pathogenesis resembles that of *B. bovis* in that mechanisms other than a haemolytic anaemia appear to be involved. However, in contrast with other animals, infection is more frequent in young dogs than in older animals. The clinical picture of dogs suffering from babesiosis is diverse and may follow a hyperacute, acute, or chronic course. Experimental infection of dogs with *B. canis* isolates from geographically different areas reveals different pathology which suggest that the aetiology of the disease caused by these isolates is different. Mildly affected animals develop anaemia and fever, are lethargic and have poor appetite. They show no visible signs of jaundice or haemoglobinuria and recover after a few days. More severe cases show a wide variety of signs, including severe depression, salivation, ► [vomiting](#), diarrhoea, jaundice and haemoglobinuria or haematuria. Pulmonary involvement occurs frequently with quickened respirations and frothy blood-stained spittle. ► [Anorexia](#) and ► [weight loss](#) may be persistent. Nervous signs may occur. Infections with *B. gibsoni* are less severe and often resemble an uncomplicated haemolytic anaemia.

Other Species

In most cases, babesial infections of other vertebrate host species are mild or clinically inapparent. However, severe reactions have been described, e.g., during *B. perroncitoi* infections in pigs and *B. felis* infections in cats.

Vaccination

The ticks responsible for transmission of cattle babesiosis are, particularly in Australia, resistant against most of the commercial acaricides, so that vaccination against the parasite is the only means of fighting the disease. It has been known for a long time that cattle can develop a prominent and long-lasting premunity against the parasite after recovery from babesia infection. From 1897 until the mid-1960s blood from recovered cattle was used as a simple blood vaccine. More recently this

live vaccine was refined by making the *B. bovis* parasite less virulent, passing it through splenectomized calves, and diluting the erythrocytes in a cell-free, plasma-like medium. This live vaccine was mainly produced and used in Australia but was also and still is used in Africa. About 10^7 parasites are administered per vaccination. The vaccine has a short half-life of about 6 days and, like most live vaccines, its quality can vary batch to batch. Live vaccines prepared in splenectomized calves are used with success in Israel against *Babesia bovis*, *B. bigemina* and *Anaplasma centrale*. They have been proven to be better than vaccines prepared from tissue cultures. The vaccines are stored and dispatched to the field in a concentrated frozen state. The extensive use of the same type of vaccine in Australia from 1959 to 1996, with 27 million doses has been recently reviewed by Callow et al. in 1997 with favourable results. However, this dependence of cold chain facilities is an insurmountable difficulty for poor and tropical areas of Africa and South America in the use of attenuated live vaccines. The search for alternative vaccines has been developed, such as attempts to use irradiated parasites with ^{60}Co with satisfactory results. Efforts to produce parasite extracts or fractions to be used as vaccines have also failed. A breakthrough in the search for a defined vaccine came when it became possible to produce *B. bovis* in a candle-jaw culture system used for growing *Plasmodium falciparum*. Parasites and culture supernatant, which contains soluble parasite exo-antigens, became available in large quantities and both produced protective immunity in cattle. Lately purified *B. bovis* antigens have been successfully used in animal vaccination trials with reference to the ability to induce protection against heterologous strains challenge. These types of vaccines have been used also in tropical areas of India and Brazil with success. However, antigen polymorphism of exo-antigens is a limiting factor for generalization of commercially available vaccines of this type.

There is only a vaccine against *B. canis* commercially available (Pirodog[®]) based on culture-derived antigens. Vaccination, however, has to be repeated regularly and induces poor protection against heterologous *B. canis* parasites.

A second generation of controlled babesiosis vaccines by gene technology methods is being intensively pursued in various laboratories. A large number of antigens to be used in subunit vaccines have been identified and cloned. However, again, antigenic polymorphism and lack of knowledge on the immune effector mechanisms responsible for protection are limiting factors for preparing practically useful recombinant or synthetic vaccines which can be used in mass vaccinations.

A 37 kDa glycoprotein of *B. bigemina* has been recently identified as the major component of a protective fraction obtained from cultures of these parasites.

Therapy

► [Babesiocidal Drugs](#).

Babesiosis, Man

Synonyms

[Piroplasmosis](#)

General Information

Babesiosis is usually contracted accidentally from the bite of an ixodid tick which transmits ► [Babesia](#) spp., an unpigmented protozoan multiplying in the red blood cell, usually in an asplenic individual. Several species of ► [Babesia](#) give rise to natural infections in cattle, other domestic animals, and field mice, on which one stage of the ► [ticks](#) normally feeds (► [Babesiosis, Animals](#)). Transmission to man occurs in the next stage. *Ixodes dammini* and *I. ricinus* are the principal vectors of *Babesia microti* which is zoonotic in New York State and Massachusetts. *Ixodes ricinus* transmits *B. divergens*. Most European cases of human babesiosis are caused by *Babesia divergens*. In humans the *Babesia* spp. undergo ► [binary fission](#) and often are located at the periphery of mature red blood cells, which are destroyed without production of insoluble pigment.

Pathology

Bilirubinemia, jaundice, hemoglobinuria, fever, and hematuria often accompany heavy infections of humans with *B. divergens* of cattle or *B. microti* of rodents. However, many infections appear to pass asymptotically. The infection is lethal in splenectomized individuals but it is very rare and is restricted to small isolated endemic areas.

Main Clinical Symptoms

Abdominal symptoms, ► [diarrhoea](#), continuous fevers of 40–41 °C, ► [anaemia](#), death.

Incubation Period

1–4 weeks.

Prepatent Period

1 week.

Patent Period

1 year.

Diagnosis

Microscopical determination of blood stages in Giemsa-stained smear preparations (pigment does never occur), ► [Serology](#).

Prophylaxis

Avoid the bite of ticks.

Therapy

Treatment see ► [Babesiocidal Drugs](#), combined with blood transfusions.

Baermann, Gustav Karl Theodor Friedrich (1877–1950)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

German physician, discoverer of the Baermann funnel to separate worm larvae from feces.

Baer's Disk

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Opisthaptor

Named by Baer (Swiss biologist). Hookless hold-fast organ of ► *Aspidobothrea*; in adult worms it covers nearly the whole ventral side.

Baermann's Larval Technique

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Method to eliminate, e.g., lungworm larvae from feces (Fig. 1). Larvae in lamp-heated feces wander to the aqueous side at the bottom and fall into the water, from where they are taken and studied by light microscope.

Baermann's Larval Technique, Fig. 1 DR of two aspects of the Baermann funnel which is used to obtain living larvae from feces

Baggage Malaria

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Other term for ► [airport malaria](#).

Baker's Itch

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Baker's itch or baker's scabies: allergic skin reaction of people coming in contact to flour or cereals that are contaminated with mites.

Balamuthia mandrillaris

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Free-living amoeba, which is found in fresh water ponds and in soil. This species, which is the only one of this genus that parasitizes in humans, leads to a so-called granulomatic amoebic encephalitis (GAE). Its life cycle runs like that of ► [Acanthamoeba castellanii](#).

Balamuthia mandrillaris: Public Health Concern

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The documented number of human infections with the opportunistic, free-living amoeba ► [Balamuthia mandrillaris](#) has increased constantly. Since the disease (BAE = *Balamuthia* amebic encephalitis infection) is difficult to detect, it must be feared that this disease has become already a major concern. Lorenzo-Morales et al. (2013) give a survey on reported cases, novel diagnostic tools, and successful therapeutic approaches.

Balantidiasis, Man

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Disease due to infections with the porcine ciliate ► [Balantidium coli](#) via oral uptake of cysts from feces.

Main Clinical Symptoms

► [Diarrhoea](#), nausea, obstipation.

Balantidiasis, Man, Fig. 1 Trophozoite of *Balantidium coli* at the intestinal wall

Incubation Period

Days to weeks.

Prepatent Period

4 days to weeks.

Patent Period

Years.

Diagnosis

Microscopic determination of cysts and ► [trophozoites](#) in fecal smears (Fig. 1).

Prophylaxis

Avoid contact with human or pork feces.

Therapy

Treatment, see ► [Antidiarrheal and Antitrichomoniasis Drugs](#).

Balantidium

Name

Greek: *balantion* = sack, *kolon* = terminal intestine.

Genus of trichostomatid ciliates (Ciliophores), the species of which live in the gut of many host species (e.g., ► [Balantidium coli](#) in pigs and humans, *B. depressum* in a mollusc (*Pila*), *B. caviae* in guinea pigs, and many species in freshwater and saltwater fish or in amphibia). Their size is often rather large (50 × 70 μm), they are characterized by an anterior vestibulum, a cystostome-cytopharyngeal complex, several contractile vacuoles, a spherical small micronucleus besides a half-moon-shaped macronucleus and the lack of typical mitochondria. However, they possess hydrogenosomes.

Balantidium coli

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *balantion* = small sack; *kolon* = terminal portion of intestine.

Geographic Distribution

Worldwide, mainly in porcines, rarely also in humans (less than 1,000 proven cases per year).

Balantidium coli, Fig. 1 Life cycle of *Balantidium coli* in the cecum and colon of humans, pigs, rodents, and many mammals. 1 Cysts of 40–60 μm diameter are excreted with the feces. The ► **macronucleus** of this species is sausage shaped. 2 Cysts are orally ingested with food by the new host. In the intestine, the ► **trophozoites** hatch from the cysts and grow to a size of $150 \times 100 \mu\text{m}$. 2.1 The trophozoite is reproduced by repeated transverse binary

fissions. ► **Conjugation** has been observed, but may occur only rarely in man. In mammals, the trophozoites may initiate *lesions* and *ulcers* of the intestine. 3 Encystment is initiated by ► **dehydration** of feces as they pass posteriad in the rectum. Trophozoites may also encyst after being passed in feces. CI ► **cilia**, CW cyst wall, CY cytopharynx, MA macronucleus, MI ► **micronucleus** (for other species of ► **Ciliophora** see ► **Ciliophora**/Table 1)

Biology/Morphology

B. coli reach a size of 50–150 μm and live in the caeca and in the colon of their hosts. This parasite belongs to the trichostomid ciliates (Ciliophora) and is characterized by an anterior vestibulum, a cytostome-cytopharyngeal complex, several contractile vacuoles, a small/spherical micronucleus, a large macronucleus, and the lack of typical mitochondria. The surface is covered by typical cilia in regular rows which allow a significant mobility in the intestinal fluid. Reproduction occurs by binary cross-directed division, while sexual processes are involved during the rarely seen so-called conjugation, during which wandering nuclei are exchanged via a cytoplasmic bridge being formed for a short time between two

trophozoites. It was noted that some trophozoites may enter the intestinal wall. Transmission of this parasite occurs by oral uptake of cysts, the wall of which is excreted by trophozoites, which then reduce their cilia (Figs. 1, 2, 3, and 4). These cysts reach a size of 50–70 μm .

Symptoms of Disease

Man (balantidiasis)

Mainly, humans working in pig elevation or in slaughter houses are infected. In most cases symptoms of disease do not appear. However, in cases of a predisposition or any immunosuppression, symptoms of disease may occur after an incubation period of about 4 days. As in bacteria-derived

Balantidium coli, Fig. 2 Light micrograph of *B. coli* prior to entering the intestinal wall

Balantidium coli, Fig. 3 *B. coli* stage inside the intestinal wall in division

intestinal diseases, spastic slimy diarrheas may occur 8–12 times per day. In cases of peritonitis even bloody stools may occur. Due to the huge loss of water, infected persons may suffer from dizziness and nausea. Due to higher rates of parasites that had entered the peritoneum (rare) cases of death had been reported.

Animals (balantidosis)

Pigs mainly suffer from heavy and numerous watery-slimy diarrheas leading to typhlitis and colitis. Due to high loss of intestinal fluids the animals show considerable loss of weight and weakness. Young pigs are in general only rarely infected, while pigs over 4 weeks show infection rates up to 100 %. This is a sign that *B. coli* is only a facultative agent of disease. Heavily infected animals, however, show numerous hemorrhagies in the colon and even in the stomach.

Diagnosis

Microscopic determination of cysts by fecal standard techniques such as M.I.F., S.A.F., or flotation.

Infection Route

Oral uptake of cysts from pig feces (farmers, butchers, other farmed pigs, etc.).

Prophylaxis

Avoid contact with human or pig feces.

Incubation Period

Days up to weeks.

Prepatent Period

Four to seven days.

Patent Period

Eventually, years in nonsymptomatic infections.

Balantidium coli,**Fig. 4** *B. coli* cyst stage inside the intestinal fluid

B

Treatment

- (a) Pigs: no safe medical cure available; symptomatically: tetracyclines or trimethoprim plus sulfonamids
- (b) Humans: Metronidazole (3×750 mg/day for adults; 35–50 mg/kg bodyweight for children) divided in three dosages per day for 5 days or tetracyclines (4×500 mg/day) for 10 days

Balantidium duodenii

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Parasite ciliate in the intestine of the common brown frog *Rana temporaria*, which shows a unique morphology being flattened along the dorso-ventral axis. It is proposed to belong to the newly created genus *Balantidiopsis*.

Balantidium Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Besides the typical human parasite ► *Balantidium coli* more than 80 further species are described to belong to this genus *Balantidium*. These species parasitize in the intestines of numerous vertebrates (mammals, birds, reptiles, amphibians, fish) and even in invertebrates. Thus there have been described *B. duodenii*, in frogs (*Ranatemporaria*), *B. entozoon*, *B. xenopi*, *B. honguerensis* (in amphibian), *B. polyvacuolum*, *B. ctenopharyngodonis*, *B. macrodextroral*, *B. jocularum* (in fish).

Barnacles

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Trivial name for the group of Cirripedia, which
live as parasites (as larvae and adults) attached to
their mostly marine hosts.

Acorn barnacles such as *Chelonibia patula*
(on the shells of crabs), *C. testudiarum* (on the
carapace of turtles), or *Platylepas helastylus*
(embedded in the skin of turtles and dugong)
may live as parasites. They belong to the suborder
Balanomorpha.

Goose or stalked barnacles are attached usu-
ally to floating organisms/material (e.g., *Lepas*
anatifera).

Typical parasitic barnacles (e.g., *Sacculina*
species) have become internal parasites of crabs

and are recognized by the large, leathery, egg producing sac being produced under the crab’s abdomen.

Bartonella Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Bartonella spp. (formerly *Rochalimea* spp.) are microaerophilic, facultatively intracellular, gram-negative, rod-shaped bacteria, which may infect animals and humans. Some of them are transmitted by vectors such as ► ticks, ► mites, ► fleas, body lice, or ► sandflies and thus eventually introduce severe diseases (Table 1).

Bartonella Species, Table 1 *Bartonella* species (selection)

Species	Hosts	Vectors	Diseases
<i>B. bacilliformis</i>	Humans	Sandflies	Carrion disease, Oroya fever, Verrugia peruana
<i>B. clarridgeiae</i>	Cats	Fleas	Cat scratch disease
<i>B. henselae</i>	Cats	Fleas, ticks	Cat scratch disease
<i>B. quintana</i>	Humans	Body lice	Five days fever
<i>B. vinsonii berkhoffi</i>	Dogs	Ticks	Not defined
<i>B. vinsonii vinsonii</i>	Mice	Mites	Not defined

Other name for chiclero's ulcer, a form of cutaneous leishmaniasis.

Baycox

Heinz Mehlhorn¹ and Gisela Greif²

¹Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

²Bayer Animal Health GmbH, Global Drug Discovery, Leverkusen, Germany

Baycox is a trade name of a very effective, broad-spectrum metaphylactically acting coccidiocidal product containing the compound ► [toltrazuril](#), which belongs to the triazinetriones. It eliminates oocyst excretions, since it kills all intracellular stages such as schizonts as well as gamonts. Biochemically it blocks the respiratory chain of mitochondria, the pyrimidine synthesis, the dihydrofolate reductase, and the dihydroorotate-cytochrome c reductase and disturbs the D1 protein of the photosystem II and EtCyp105. The following products have an authorization status: Baycox[®] poultry in 86 countries, Baycox[®] piglet in 74 countries, Baycox[®] cattle in 34 countries, and Baycox[®] sheep in 17 countries (Gottstein et al. 2005; Greif 2000; Greif et al. 2001; Haberkorn et al. 2001; Mehlhorn et al. 1984, 1988; Schmahl et al. 1988).

Baycox Product Authorization Status: Country List

1. Baycox Oral Sol (2.5 % Tolt) chicken/turkey
Dosing: 7 mg/kg body weight for 2 treatment days in drinking water
First launch: Mexico (1985)
Albania, Algeria, Argentina, Australia, Austria, Azerbaijan, Belarus, Belgium, Brazil, Bulgaria, Chile, China, Colombia, Costa Rica, Croatia, Cuba, Cyprus, the Czech Republic, Denmark, the Dominican Republic, Ecuador, Egypt, El Salvador, Estonia, France, Georgia, Germany, Ghana, Greece, Guatemala, Honduras, Hungary, India, Indonesia, Iran, Ireland, Italy, Kazakhstan, Kenya, Korea (South), Kuwait, Kyrgyzstan, Luxembourg,

Macedonia, Malawi, Malaysia, Mexico, Moldavia, Morocco, Namibia, the Netherlands, New Zealand, Nicaragua, Nigeria, Norway, Oman, Pakistan, Panama, Peru, the Philippines, Poland, Portugal, Qatar, Romania, the Russian Federation, Serbia, Sierra Leone, Slovakia, Slovenia, South Africa, Spain, Sri Lanka, Sweden, Switzerland, Taiwan, Tanzania, Thailand, Turkey, Uganda, Ukraine, the United Kingdom, Venezuela, Vietnam, Yemen, Zambia, Zimbabwe

2. Baycox Susp (5 % Tolt) piglet
Dosing: 20 mg/kg body weight, 1 treatment only during the first week of life
First launch: Australia (1998)
Australia, Austria, Belarus, Belgium, Canada, Costa Rica, Cuba, Cyprus, the Czech Republic, Denmark, the Dominican Republic, El Salvador, Estonia, Finland, France, Germany, Greece, Guatemala, Iceland, Ireland, Italy, Japan, Kazakhstan, Latvia, Lithuania, Luxembourg, Mexico, Moldavia, the Netherlands, New Zealand, Norway, the Philippines, Poland, Portugal, Qatar, the Russian Federation, Sierra Leone, Slovakia, Slovenia, South Africa, Spain, Sweden, Taiwan, Ukraine, the United Kingdom, Vietnam, Zambia
3. Baycox Susp (5 % Tolt) cattle
15 mg/kg body weight, 1 metaphylactic treatment
First launch: Denmark (2006)
Albania, Australia, Austria, Belgium, Bulgaria, Croatia, Cyprus, the Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Japan, Latvia, Lithuania, Luxembourg, the Netherlands, New Zealand, Norway, Poland, Portugal, Romania, Serbia, Slovakia, Slovenia, Spain, Sweden, the United Kingdom
4. Baycox Susp (5 % Tolt) sheep
20 mg/kg body weight, 1 metaphylactic treatment
First launch: Norway (2007)
Belgium, Cyprus, Denmark, Finland, France, Germany, Greece, Iceland, Ireland, Italy, Luxembourg, the Netherlands, Norway, Portugal, Spain, Sweden, the United Arab Emirates, the United Kingdom

Geographic Distribution/Epidemiology

Many countries, where raccoons occur. Other species in China (in Panda bears)

The following *Baylisascaris* species are described in their final hosts:

Species	Final host	Distribution
<i>B. ailuri</i>	Red panda	China
<i>B. columnaris</i>	Skunks	North America
<i>B. devosi</i>	Mustelids	North America, Eastern Europe
<i>B. laevis</i>	Rodents	North America
<i>B. melis</i>	Badger	Europe
<i>B. procyonis</i>	Raccoons	North, Central America, Central Europe, Asia
<i>B. schroederi</i>	Giant panda	China
<i>B. tasmaniensis</i>	Marsupials	Tasmania
<i>B. transfuga</i>	Bears	Arctic, North America, Europe, Asia

Baylisascaris procyonis

Ascarid nematode of racoons; life cycle compare ► [Ascaris](#); leads to ► [larva migrans](#) in humans.

Baylisascaris procyonis and Related Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

English, Bayli = girl name; Greek, *askaris* (internal worm described in literature of Aristoteles)

Morphology/Life Cycle

The discovery and the evaluation of the importance of the species of the genus *Baylisascaris* are rather young. Since the first description in the year 1931 (in the Zoo of New York), it took until 1968 when the genus *Baylisascaris* was defined followed by description of species parasitizing lower mammals (e.g., *B. columnaris*, *B. melis* in skunks and badgers). *B. procyonis* of raccoons became especially important due to fatal infections in humans. The adults of this species (♀ = 14–28 cm, ♂ = 7–12 cm) live in the intestine, where the females produce large numbers of dark brown, ellipsoidal unembryonated eggs (63 × 88 µm × 50–70 µm). Outside the body it takes 2–4 weeks, until the infectious larva 2 is formed inside the egg, which remains viable in moist soil for years. These eggs are infectious directly for raccoons, for small mammals (rodents, woodchucks, rabbits), for birds, and also for humans. However, only in raccoons the mature adults are formed. The larvae 2 enter the intestinal mucosa for a while, before they finally

Baylisascaris procyonis and Related Species, Fig. 1 Stamp showing the final host

reemerge into the lumen of the intestine for final development into the adult stage, which is reached about 60 days after infection. If raccoons ingest infected intermediate hosts, the larvae reach also maturity in raccoons (Fig. 1). Humans may become infected, too. The larvae then start migration throughout the body.

Symptoms of Disease (Raccoons)

Infections with *B. procyonis* remain in most cases symptomless; however, extremely high worm burdens may also cause severe intestinal obstruction and death. **Humans:** It turned out that the species of raccoons (*B. procyonis*) and those of the giant panda bears (*B. schroederi*), of the red panda (*B. ailuri*), and of the polar bear (*B. transfuga*) are not only able to establish patent infections in the intestines of their final hosts (in case they take up embryonated eggs) but also are able to induce “**larva migrans disease**” due to wandering larvae in many nonspecific hosts including humans. Thus, the number of reported clinical visceral (VLM), ocular (OLM), and neural (NLM) larva migrans is constantly increasing. This threatens especially in China the existence of Panda bear species and also endangers health of humans as does the ascarid worm of dogs

(► *Toxocara canis*). Although definitively well-described cases of humans are rare, many infected persons died.

Diagnosis (Raccoons and Other Final Hosts of Other Species)

Microscopical determination of the typical eggs (ascarid type, measuring $63 \times 88 \mu\text{m} \times 50\text{--}70 \mu\text{m}$) after the use of concentration methods (e.g., S.A.F.C.). **Humans:** Since migrating larvae are difficult to diagnose with microscopical techniques, serological methods must be used (e.g., ELISA, Western blot).

Infection

Ingestion of eggs containing an infectious larva
2 containing eggs within contaminated food or water.

Prophylaxis

Avoid contact to feces of raccoons and the feces of other final hosts of the other species.

Incubation Period (Raccoons)

Six to eight weeks or more, if symptoms occur.

Humans: 1–2 weeks.

Prepatent Period (Raccoons)

Five to six weeks.

Patency

Eventually years.

Treatment (Humans)

Therapy of this disease due to wandering larvae is not yet very successful in humans, although promising trials had been done with thiabendazole (Minzolum®- 2×25 mg/kg bodyweight daily for 5–7 days) or albendazole (10 mg/kg bodyweight daily for 5 days) always accompanied by corticosteroids to avoid allergic reactions. Recent research projects of Xie et al. (2013) showed that inorganic pyrophosphatases (PPases) are needed for the development and for molting of *Baylisascaris* larvae (as well as for other nematodes). Thus, these PPases are a successful target for vaccination, which is already tested in experimentally infected mice.

Name

Greek: *bdallein* = sucking.

Genus of mites, synonymous with *Ornithonyssus* and *Liponyssus*.

Beauveria

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of entomopathogenic fungi, the species of which are used as biological insecticides to control growth of anophelid mosquitoes. If adult mosquitoes get contact with conidia of *Beauveria*, they die within 24 h.

Bed Bug Control

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Occurrence of bed bugs (► *Cimex lectularius*, Fig. 1) became a major concern not only in

housing facilities of families with low income but also in hotels of any grading and in many other domicils. Furthermore aircrafts are more and more endangered, especially since methyl bromide has been withdrawn in Europe. Heat control in different forms of aircraft was considered as a direct means to replace methyl bromide reaching efficacy rates of 92–95 %; however, this procedure needs time and recirculating repetitions of the treatment. Thus this method is too expensive. On the other hand, pyrethroid resistance in ► *Cimex lectularius* is progressing in many countries of the world. Especially knockdown resistance (kdr) to pyrethroids has been shown to be associated with the occurrence of two-point-mutations in the voltage-gated sodium channel α -subunit gene. However, resistances have also been described against carbamates and even against organophosphates. The use of diatomaceous earth (dusts) were successfully tested, but may lead to severe breathing problems of people living in such houses. Similar side effects may occur, if essential oils, which are effective, are used. The product MiteStop®, which leads to drying of the bed bug's surface, kills them softly. It was developed by Alpha-Biocare GmbH in Germany (www.alphabiocare.de). In any way, bed bugs are of increasing impact and recent control success is only given, if they come into direct contact with the insecticidal products.

Bed Bugs Records

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Life Time

Six months up to 1 year.

Size

Full fed females reach up to 1 cm in length.

Feeding Time

Up to 10 min every 2–3 days.

Food (=Blood) Uptake

Up to sevenfold of their body weight.

Starvation

Up to 40 weeks.

Reproduction Rate

Females lay daily 1–12 eggs, in total up to 200.

Development of Larvae

At room temperature it takes about 14 days until larvae hatch from the eggs.

Individual Development

The five larval stages develop within 6–7 weeks into adult male or female stages.

Means of Recognition

Excretion of so-called aggregation pheromones help to form large quantities of animals at hidden places in a house.

Means of Protection

Excretion of so-called alert pheromones of a wounded animal introduces individual hiding, thus masses of bugs run away and at least some will survive any attack.

Occurrence

Worldwide in human domiciles, but also in adjacent nests of birds or resting places of bats.

Endurance

Bugs may survive in very cold surroundings but also room temperatures of 50 °C. They have developed resistances against insecticides.

Propagation

Domiciles are mostly infested by bugs, if eggs are imported with luggage (from holidays) or with furniture from foreign owners.

Protection

Keep luggage closed during holidays and clean intensively in case of buying second-hand furniture.

General Information

Parasites have evolved a wide range of subtle and sensitive mechanisms for locating and invading their hosts, for avoiding and resisting host defense systems and for acquiring resources that are not given to them voluntarily.

In response, the host has evolved remarkable defense strategies to avoid becoming infected and if they fail, to reduce the detrimental impact of the parasites on their individual bodies but also to improve the gene pool of their offspring by choosing mates with high resistance against parasites. In the context of parasite-driven sexual selection it is interesting to note that, according to the ► *Red Queen Hypothesis*, the advantage of sex and recombination – compared to parthenogenetic reproduction – is, for the host, the means for producing rare offspring that may escape infection and, for the parasite, the means for tracking these genotypes as they become common. Consequently, the evolutionary arms race between parasite and host is getting increasingly sophisticated.

In most of these host–parasite interactions, behavioral aspects play an important role. It is noteworthy, however, that the word behavior is used in different senses. If parasites shed their ► *glycocalyx*, which has become loaded with antibodies, or when they switch the genes involved in their antigenetic variance, these actions are named behavior by certain authors. The scope of this chapter does not include such physiological actions and responses but is rather confined to activities that are carried out by the whole parasite or host body, or at least by certain external extremities or organs of it.

For many years the well-known behavioral changes displayed by ants infected with ► *Dicrocoelium dendriticum* have fascinated parasitologists and behavioral ecologists. A vast number of papers reporting behavioral alterations in various infected hosts, mainly intermediate hosts,

have appeared since then. Parasitologists were eager to detect the physiological mechanisms behind the abnormal behavior but unfortunately they were not all that successful, except for a few cases where agents such as the neurotransmitter serotonin could be named as being involved in the behavioral change. Behaviorists on the other hand were keen on debating the theoretical aspects of the phenomenon. In a recent review on parasite transmission authors succeeded in combining both approaches and also suggest criteria for the differentiation between adaptive behavioral changes and such alterations which are just pathological side effects of infection, reflecting, for instance, an altered ► [energy metabolism](#).

As pointed out in a review by Poulin, researchers often use the “adaptation” label for host behavioral changes, based on their intuition. He suggests that altered host behaviors following infection can only be considered adaptive in an evolutionary sense if they satisfy certain conditions: (1) they must be complex; (2) they must show signs of purposive design; (3) they are more likely to be adaptations if they have arisen independently in several lineages of hosts or parasites; and (4) they must be shown to increase the fitness of either the host or the parasite.

A landmark paper which opened an entirely new line of research appeared in 1982: ► [Hamilton and Zuk's hypothesis](#) that there should be a relationship between a species' parasite load and its sexual showiness such as a colorful plumage. In female mate choice, an individual male's resistance to parasites should be expressed in exterior secondary sexual characters which would allow a female to select parasite-resistant genes for her kin (parasite-mediated sexual selection). Subsequently, this novel concept has been manifoldly confirmed and partly disputed.

The present chapter – written from the host-parasite-interactions viewpoint of its author – aims to describe parasitological items involving the behavior of hosts and parasites, and to focus on new trends in the subject which have come up within the past few years. Such aspects that do fit into the scope of this review but are treated in other chapters have not been considered here.

Alterations of Host's Behavior Facilitating Parasite Transmission

Concerning **trophically transmitted parasites** in their intermediate hosts a few, rather early, descriptions provided conspicuous and astonishing examples of behavioral changes in a host. For instance, there was the discovery of the life cycle of ► [*Dicrocoelium dendriticum*](#) in which a specialized metacercarial stage, the ► [brain worm](#), induces an ant to seek an exposed position on a blade of grass where it stays, thus making itself vulnerable to predation by grazing ungulates. Sporocysts of *Leucochloridium* spp. were shown to mimic animals serving as food-items of warblers, the final bird hosts of the parasite, by forcing the snail intermediate host's tentacles to change size and shape, attain a showy color and perform pulsating movements. Later on, the literature on the behavior of parasitized intermediate hosts of parasites transmitted to final hosts via the food chain became very voluminous. Mostly authors were tempted to assume that alterations in ranging, foraging, cryptic, or antipredator behavior followed a purposive design, either benefiting the parasite in its transmission or the host (which is less frequently postulated).

Theoretically, the parasite can manipulate its host's behavior directly or it can influence its decision-making by imposing a constraint or stress, for instance by causing a drain of energy. Hunger-induced decrease of antipredator behavior induced by a parasite seems to be very common. In 3-spined sticklebacks (*Gasterosteus aculeatus*) infected by *Schistocephalus solidus* the energy flow into the large plerocercoids parasitizing in the peritoneal cavity of the fish result in higher energetic requirements and a higher oxygen demand. Consequently, time spent feeding away from a shelter is prolonged, combined with a reduced aversion to the risk of predation and a shift in habitat preference emerging to the surface of the water where the availability of oxygen is best.

Toxoplasma gondii, for instance, is known to induce various behavioral alterations in its rodent intermediate hosts, but they do not seem to be driven by hunger. In addition to memory

impairment, the propensity to explore novel stimuli in their environment is higher than in uninfected individuals. Infected rats are more active and more easily trapped. Interestingly, this altered perception of predation risk can be prevented not just by anti-*T. gondii* drugs but also by antipsychotic drugs.

In human patients (accidental hosts of *T. gondii*) latent toxoplasmosis, i.e., the lifelong presence of *Toxoplasma* cysts in neural and muscular tissues, leads to a prolongation of reaction times and reduced concentration, and accordingly such infected subjects have a higher risk of committing an accident than toxoplasmosis-negative subjects.

Among the trophically transmitted parasites acanthocephalans offer several good examples of complex and purposive alterations in the behavior of the host, leading to an increased probability that the larvae of the parasites will be transmitted to their final hosts. According to the often-quoted papers by Bethel and Holmes, the altered behavior of *Gammarus lacustris* only becomes apparent when the larvae of *Polymorphus paradoxus* reach their infectivity to the definitive host. Gammarids infected with infectious cystacanths of this species respond to disturbance by approaching the water surface and clinging to solid objects. Uninfected conspecifics are less sensitive to disturbance; when they are disturbed, they dive toward the bottom and burrow themselves into the mud. Later on Helluy and Holmes, after experimenting with different neurotransmitters known to play a role in crustacean behavior, offered an explanation of the altered behavior. They succeeded in demonstrating that the clinging behavior is influenced by serotonin, the injection of which also induced the same behavior in uninfected gammarids as in infected individuals.

Among acanthocephalans the induced abnormal behavior is often combined with a conspicuous orange or yellow color of the cystacanths, which is visible through the ► [cuticle](#) of the crustacean intermediate host, making the alteration more complex and purposive in terms of an increased predation probability by a final host; this has been demonstrated for several acanthocephalan species. In *Caecidotea intermedius*

(formerly *Asellus intermedius*), infected with *Acanthocephalus dirus*, it could be shown that the decreased antipredator behavior of the infected isopods was obviously not simply due to increased energy demands since the time spent away from a refuge, when a predator was present, was not related to the location of the food offered.

The literature on behavioral changes of intermediate hosts of trophically transmitted parasites promoting their transmission to suitable final hosts – often referred to as favorization – has become rather voluminous.

Regarding behavioral alterations of final hosts of parasites and of parasites with monoxenic life cycles little information is available.

Mice subclinically infected with the monoxenic coccidian *Eimeria vermiformis* spent a significantly greater amount of time near to a source of cat odors and generally showed less predator-induced fear compared to uninfected controls. The altered behavior could not be modulated by treatment of the mice with morphine. Interestingly, in this case the resulting increased vulnerability of the infected mice to predation is not beneficial to the parasite which uses mice as the only host. Thus, behavioral changes do not always have to show a purposive direction that increases the probability of transmission of a parasite.

Often infected hosts are subjected to neuromodulatory responses leading to reduced spatial learning (mice infected with the monoxenic nematode ► [Heligmosomoides polygyrus](#)). Also, *Schistosoma mansoni* infection in humans and animals induces abnormal neurobehavioral responses, following granuloma formation. In infected mice the exploratory activity and the pain response on the host plate are markedly altered. Also increased sniffing and grooming of the infected mice can be noted. In malnourished schoolchildren the degree of infection with ► [Ascaris lumbricoides](#) was correlated with varying cognitive behaviors.

Human adults infected with *Dracunculus medinensis* revealed lowered sexual activity and poor maternal attention (in females).

All these behavioral changes seem to be side effects of pathology reflecting incomplete reciprocal host–parasite adaptations and thus cannot be considered adaptive in an evolutionary sense.

Nontrophically transmitted parasites may manipulate host behavior in a way aiming at an altered habitat preference benefiting their life cycle requirements. Mermithid nematodes as well as Nematomorpha are capable of driving their terrestrial hosts into water where the parasites can complete their life cycles as free-living adults. Nematomorphs achieve this by altering host transmitters, but the mechanisms used by mermithids have remained less understood. The supralittoral marine amphipod *Talorchestia quoyana* when infected with the mermithid *Thaumamermis zealandica*, seeks water-saturated sand where it burrows more deeply than uninfected individuals. An increase of host haemolymph osmolarity seems to induce “thirst” explaining why parasitized amphipods seek wet substrates.

Concerning **parasites transmitted by blood-sucking vectors**, behavioral changes affecting the vertebrate hosts as well as the arthropod vectors have been described.

Oxen infected with *Trypanosoma congolense* were about 70 % more attractive to the ► *Glossina pallidipes* vector than uninfected controls or controls infected with *T. vivax*; and the feeding success of the tsetse flies on the oxen infected with *T. congolense* was approximately 60 % greater than on oxen of the other two groups. Both differences were discussed in relation to reduced antifly movements and vasodilatation induced by *T. congolense* in the mammalian host. The transmission of the parasite, however, also seems to be promoted by behavioral changes affecting the insect vector. ► *Epimastigotes* of *T. congolense* attach themselves by means of ► *hemidesmosomes* to the labral mechanoreceptors of the vector, thus impairing the sensory function and feeding behavior of the infected flies. The impairment of normal receptor function, plus the accumulation of trypanosomes in the labrum, also decreases the flow within the food canal. Infected flies probe more frequently and take longer to engorge than uninfected flies. These features

have been calculated to increase the transmission rates for the parasites.

Furthermore, infection of ► “kissing bugs” (Reduviidae) with *T. cruzi* reduced the time to detect potential hosts in comparison to control insects. Infected bugs bit about twice as often as uninfected nymphs and defecated 8 min after the last blood meal whereas uninfected individuals needed 11 min. And from mosquitos infected with *Plasmodium* spp. we know that appetite for blood is stimulated by the infection in themselves and their vertebrate hosts.

Castration, Sexual Reversal, Sex Ratio Distortion

As already mentioned, parasitized hosts are often restricted in their mating behavior and in many cases do not show any sexual behavior at all, which may result from partial or complete castration, more frequently affecting intermediate hosts than final hosts. Castrated, nonreproducing males, like green crabs (*Carcinus maenas*) infected by the monoxenic rhizocephalan barnacle *Sacculina carcini*, tend to become feminized in their phenotype.

But in other host–parasite associations, best described from gammarid crustaceans, feminized males behave as genetic females and can even produce offspring. Once thought to be a rare phenomenon, sex-ratio distortion by parasites is now known to be common in many (mostly arthropod) invertebrates.

Among microsporidians many species undergo partly or even solely vertical transmission. This means that the parasite is transovarially transmitted in the cytoplasm of the eggs from mother to offspring. Infected male embryos become feminized which increases the transmission base to future host generations by converting males, which cannot transmit the parasite in their sperm, into females. Due to such female-biased broods combined with a high prevalence of the microsporidians, eventually host populations should collapse due to a lack of males. However, feminized males are larger than true females and accordingly are less accepted as sexual mates than the latter. Furthermore, as described from *Gammarus duebeni* infected with *Nosema*

granulosis, male (uninfected) amphipods provide uninfected, high fecundity females with more sperm than infected females.

These findings again demonstrate that parasites manipulate host behavior in order to promote their transmission, while the hosts' counter measures aim at the selection of good genes useful in resisting future parasite attacks against their progeny (good genes benefits mating, antiparasitic sexual mate choice, see below).

Behavior of the Host in Avoiding, Expelling or Eliminating Parasites

Change of Habitat

Many examples reveal how mammals temporarily change their location in response to attacks by flying insects, e.g., when reindeer enter water or scrub. A special kind of change in habitat preference in response to parasite attack appears to be roost-switching of hosts that live in groups. Bats change their day roost in response to a severe ► [ectoparasite](#) attack. High ectoparasite levels were correlated with lower body weights in lactating females. Thus roost-switching might be an important strategy for decreasing ectoparasite loads by interrupting the reproductive cycles of those parasites that spend at least part of their life cycle on the walls of the cave.

Escape and Defence Behavior

Evasive actions of hosts following attacks of ectoparasites have been described from many hosts. The effectiveness of such actions has been demonstrated. A very interesting study was carried out by Laitinen et al. Brown trout (*Salmo trutta*) and roach (*Rutilus rutilus*) were exposed to furcocercariae of a ► [Diplostomum](#) sp. that infects the eyes of fishes and to ► [xiphidiocercariae](#) of a ► [Plagiorchis](#) sp. that employs insects as second intermediate hosts. Swimming activity increased significantly in the roach exposed to *Diplostomum* ► [cercariae](#), even at very low densities, and remained high for 24–36 h after exposure. Brown trout showed no response to low cercarial numbers but responded significantly at high exposure densities. The increase in activity peaked at

2 h and returned to pre-exposure levels within 5–6 h. In contrast, exposure to the cercariae of *P. elegans* did not elicit a response in either fish. This difference in the evasive behavior of the host could be due to the adherence and penetration activity of the *Diplostomum* cercariae on the fish. On the other hand, related host species may differ in their success in preventing attacks of ectoparasites, perhaps reflecting different ecological strategies. Tadpoles of *Bufo* and *Rana* species can also make explosive movements when they sense cercariae contacting their skin. Because *Bufo* (toad) tadpoles are unpalatable to many predators they obviously have a different trade-off between predation and infection risk than *Rana* (frog) tadpoles and can afford to make more conspicuous evasive manoeuvres than the latter which can be demonstrated in the laboratory. Species-specific differences in antiparasitic behavior are also known from higher vertebrates. In cage experiments with six species of herons and one ibis, ► [mosquitoes](#) preferably fed on two of the heron species. When the birds were prevented from moving (most of their defensive behavior was directed toward protecting the legs and the feet) similar numbers of mosquitoes engorged on all the bird species.

Hygienic Behavior

Localized defecation sites as a tactic to avoid (re-) infection by gastrointestinal tract parasites are practiced by many herbivorous as well as by carnivorous hosts such as raccoons. But it remains under discussion to which extent the habit to deposit feces at latrine sites is a parasite avoidance measure or whether it also has a social function.

Avoidance of Parasite Transmission by Choosing Uninfected Sexual Mates

The parasite avoidance hypothesis, which applies to horizontally transmitted parasites (ectoparasites, venereal diseases, and directly transmitted microparasites), suggests that females reduce the probability of catching parasites by direct transmission if they choose parasite-free males. The mate's sexual ornament, its odors or acoustic signals may serve as cues in decision-

making according to the hypothesis of Hamilton and Zuk (good genes benefits mating; see below).

Distinction and Avoidance of Infected Food

Since many parasites that are transmitted to their subsequent hosts through predation strongly reduce the fitness or even the survival of these hosts, the hosts should theoretically try to recognize and avoid infected prey individuals or to exclude particular prey species entirely from their diet when alternative prey is available. In different trials, sticklebacks constantly, and under all conditions tested, consume copepods infected with the tapeworm *Schistocephalus solidus* in preference to uninfected specimens. The infected copepods were more active and easier to catch. In this case, the proceroid of the parasite inside the copepod was visually inconspicuous, but still one should expect that the pronounced pathogenicity displayed by this tapeworm in sticklebacks would have led to discriminative feeding behavior. If female sticklebacks avoid mating with parasitized males why do they accept parasitized prey? was the question that Bakker asked. He was amazed that sticklebacks did not even avoid gammarids that were marked by the shiny, orange-colored, infected larvae of the acanthocephalan *Pomphorhynchus laevis*. On the contrary, the infected gammarids were preferentially preyed upon because they possessed the conspicuous color mark that was visible through their transparent cuticle and because of their diminished photophobic behavior. This again contrasts with the high discriminating value of small dark spots (metacercariae) on the surface of fish when these fish species choose sexual mates or mates to school with. As far as can be ascertained, no positive report on the avoidance of infected prey or food by animal hosts exists. There has been some debate about an assumed trade-off between the energy gain of ingesting the easily accessible infected prey and the subsequent costs of reduced fitness. But regarding the transmission of *Leucochloridium* digeneans, the sporocyst of the parasite inside the snail's tentacle is the prey, not the snail or the tentacle. Thus, in this case no energetic trade-off could justify the uptake of this (apparent) prey.

Antiparasitic Social Mate Choice

Sexual mate choice under the auspices of parasitism has received plenty of attention but many other forms of partner choice exist where parasitism plays a role. Banded killifish, *Fundulus diaphanus*, were presented individually with a choice of "shoaling" with either of two conspecific stimulus shoals, the one consisting of fish with externally visible black spots (melanized metacercariae of *Crassiphiala bulboglossa*), the other consisting of fish without such spots. Both parasitized and unparasitized test fish significantly preferred to shoal with unparasitized stimulus shoals rather than parasitized ones. It was also shown in another experiment that killifish used black spots as an indicator for the presence of parasites when making their shoal choice. Thus, although in the case described metacercariae cannot spread from one fish to another, the decision of the fish should be interpreted as a parasite-avoidance behavior. Probably many ectoparasites that do have the ability to spread from host to host within a shoal are visually detectable by the respective fish. Furthermore, the parasitized shoal must have been exposed to the parasites and the exposure might be continuous.

Measures to Eliminate Parasites That Have Become Established

If an infection could not be prevented, the parasites can be attacked or removed by the host's behavior.

The physical removal of ectoparasites by the hosts has been well studied. Tools available for this task are, for instance, comblike cleaning claws existing in several families of birds such as herons, and in certain marsupial and lemuriform mammals. House mice (*Mus domesticus*), for instance, have specialized lower incisors (teeth) which are capable of lateral closure and can thus effectively comb ectoparasites (such as the anopluran louse, ► *Polyplax serrata*) away from the fur. Most stages of this common louse aggregate on the anterior body (mainly the head) where self-grooming is difficult. If, however, grooming is prevented by placing a collar around the neck of the mouse, ► lice and their eggs spread across the whole body, and the

number of lice may increase from 100 to more than 1,000 within 4 weeks. Within 24 h of being permitted to self-groom the number of lice and their distribution begin to return to normal. Furthermore, recent studies have revealed the adaptive significance of avian beak morphology for ectoparasite control. The shape of a bird's beak used to be interpreted in relation to its role in feeding but now it is acknowledged to play an important role in preening. Amputation experiments were carried out with domestic pigeons. When the tips, obviously an important tool in preening, of the bills were removed (which did not prevent the birds from feeding) the populations of lice in their plumage increased rapidly.

Until recently we knew rather little about the time terrestrial animals devote to grooming. Cotgreave and Clayton published data on 62 bird species. On average, the birds spent 9.2 % of the day in maintenance activities, mainly grooming (92.6 %). Interestingly, bird species known to harbor a large number of lice spend more time grooming than do host species with few lice; the time spent on preening can also be experimentally manipulated by loading ectoparasites onto them. Of course, as one may expect, parasites have also adapted to grooming and can even utilize it for their transmission, as is shown in the case of the nematode *Heligmosomoides polygyrus* in the mouse host. After infective larvae have been placed on individually housed mice, significantly higher numbers of adult worms were recovered from the small intestines of the mice that were allowed to self-groom than were recovered from those mice that had been fitted with collars to prevent self-grooming. When larvae were placed on a single mouse housed with three other untreated mice, the latter became infected, suggesting that allogrooming may also be important in parasite transmission.

Following transcontinental introductions of parasites, hosts that have not undergone coevolution with the invasive parasite may become colonized and seriously harmed due to a lack of parasite removal behavior. In hives of the Asian honey bee *Apis cerana* serving as the natural host

of the mite *Varroa destructor* (syn. *jacobsoni*), most of the infected worker brood is removed from the colony, and bees also pick up mites from their bodies. In contrast, in hives of the naive novel host *Apis mellifera* (European honey bee) infected brood is not efficiently recognized and eliminated and the grooming behavior of the workers is comparatively low.

Self-Medication

Many host species have been found to use substances (mainly plants) from their environment that are deliberately swallowed or otherwise contacted under certain circumstances. Several substances investigated seem to have detrimental effects to the parasites, and in certain cases it even seems that the use of the drugs leads to improved host fitness. Huffman correlated quantitative measures of the health of chimpanzees with observations of leaf-swallowing in an African national park. There was a significant relationship between the presence of whole leaves of certain plants and worms of adult *Oesophagostomum stephanostomum* in the dung of the apes. But later on other controversial results and discussions about the medical properties of such plants ingested by chimpanzees came up and it appeared that swallowing unchewed rough leaves rather than the drugs in them was the causative agent of the self-cure.

Behavioral Fever

Poikilothermic hosts affected by endoparasites may raise their body temperature by choosing warm and sunny microhabitats in order to improve the function of their immune system. In addition to generating behavioral fever, infected host individuals may prefer microhabitats with a lower temperature than their uninfected mates, slowing down the development of the parasites (digeneans in snails). But thus far only little and controversial literature on this subject exists. In addition, parasites are also known to manipulate their host's behavior making them select certain sites. So the distinction between both phenomena may not be easy to elucidate and further study of this topic is needed.

Host Sexual Mate Choice as an Antiparasitic Selective Mechanism

General Aspects

At breeding time, conspecifics of one sex normally compete intensively for being chosen by the other sex. Mostly, the females choose and many studies have shown that they use male signals as a basis of their choice. Hamilton and Zuk postulated that secondary sexual characteristics may allow females to select healthy, vigorous males resistant to common and harmful parasites and thus pass resistance genes on to their offspring. Thus, one of the most substantial benefits of sexual reproduction itself could be that it allows animals to rapidly react to changing environmental selection pressures such as coevolving parasites. Indeed it appears as if sexual reproduction itself is favored by selection resulting from host–parasite interactions. In different populations of a ► *dioecious* freshwater snail, showing both sexual and parthenogenic reproduction, the frequency of males was used to estimate the degree of sexual reproduction in each population. The male frequency was significantly positively correlated with the frequency of two digenetic ► *trematodes* in the snails. Since the proportion of males infected was not significantly different from that of the females, this interesting result did not appear to be an artifact. The result suggests that parasitism potentially functions as a means of frequency-dependent selection which favors the maintenance of sex. Therefore sex and recombination seems to be a definite strategy of hosts in the evolution of their resistance toward parasites. One may conclude that heritable variation in parasite resistance is maintained by coevolutionary cycles between host and parasite genotypes.

Female's Choice

Among birds, ornamental characteristics, for instance of the plumage, are often related to sexual mating. So when females pick partners to mate with, they may make their decision according to the impression they get of an ornamentation that has been directly altered by parasites, i.e., by the optical presence of the parasites themselves on the

host or by marks created by their activity. For example, female saga grouse (*Centrocercus urophasianus*) appear to reject lousy males because their airsacs, inflated during courtship, have many small black hematomas caused by the lice infestation. Males with artificial hematomas applied with a pen are also rejected by females.

More common, however, seem to be indirect adverse effects of parasites on male secondary sexual characteristics, leading to the female's preference for unparasitized males. Among captive flocks of red jungle fowl (*Gallus gallus*), roosters experimentally infected with intestinal nematodes (► *Ascaridia galli*), revealed duller combs and eyes, shorter combs and tail feathers, and paler hackle feathers upon reaching sexual maturity than did the roosters of a control group. In experimental mate choice tests, two-thirds of the females preferred unparasitized rather than parasitized roosters. Moreover, the hens made their choices according to features indirectly caused by the parasites and not according to nonsexually selected characteristics such as bill size, as evidenced by other tests.

Among many passerine birds, female mate preferences for a shiny, colorful ornamentation such as red breast are well-documented. Among yellow-hammers (*Emberiza citrinella*), for instance, male intensity of infection by the hemoprotozoan *Haemoproteus coatneyi* is reliably revealed by the bright or pale male's yellow plumage. But inconspicuous features like the size of a certain spot can also mediate mate choice. In addition, all signals seem to play a role in territorial behavior appealing to the own sex.

Acoustic cues may reflect the health and vigor of mates and competitors. Among birds, the receivers of songs can gain information relevant to mate choice and to male–male competition from the complexity, duration, and frequency of the song. Furthermore, male parasite loads were found to be correlated with the speed of an acoustic response to an intruder and the structure of the call.

Among fish too, the intensity of the red coloration as a sexually dimorphic characteristic shows relationships with parasite intensities; and in

sticklebacks (*Gasterosteus aculeatus*), the role played by male coloration in mate choice and the avoidance of parasitized males has been evidenced.

Breeding tubercles, the sexual ornamentation of many fish species, are induced by several androgens and at least one estrogen. Interestingly, among male roach and other cyprinids it was observed that the more heavily they were infected the fewer breeding tubercles they had. It was concluded that a female could potentially decode these differences in ornamentation in order to gain a sort of clinical picture of the male as her choice of mate. The few data available from male reptiles involving infection by ► *Plasmodium* spp. also show alterations in sexually dimorphic coloration combined with less courtship and territorial behavior, which negatively influences the female's choice of mate.

Interestingly, among mammals, odors seem to have the potential for decoding complex information, and this also seems to be true for major histocompatibility complex (MHC)-linked odor components: glycoproteins encoded by MHC loci under the influence of bacteria may simply degenerate to waste products small enough to become evaporating molecules in urine and feces. Urine odors of male mice (experimentally subclinically) infected with coccidians or helminths were offered to female mice in choice experiments. The females showed an overwhelming preference for the odors of the nonparasitized males.

Concerning insects, the few studies that have been conducted also suggest that certain courtship songs are indicators of male quality, and females (of crickets) responded most positively to the songs of males that proved to have high encapsulation abilities (a measure of immunity).

Interestingly, sexual signaling may be dishonest as shown from mealworm beetles. Males, when perceiving a threat to survival, may divert resources into attractiveness traits in order to maximize mating prior to death or parasitic castration which is dishonest with respect to the male's current condition.

As discussed by Wedekind, there are a lot of theories and hypotheses about benefits relating to

resistance genes and choosy females. But there is a general consent about the assumption that the maintenance of conspicuous secondary sexual characters is costly to the immune system demonstrating that a vigorous male can bear the cost of the immunosuppressant effects of androgens. Exaggerated ornamentation decreases immunocompetence. On the other hand, the bright yellows, oranges, and reds exhibited by many bichromatic birds are the products of carotenoid pigments, which are known to have health benefits. Therefore, bright colors may also be indicative of a bird's access to a superior diet or of its superior foraging ability. Testosterone is associated with a suppressed immune system in many vertebrates and the sexes differ accordingly in the blood parameters involved in immunity. The comb length of red jungle fowl, for instance, is positively correlated with the plasma testosterone level but negatively correlated with the number of lymphocytes in the blood. Male house sparrows with pronounced secondary sexual characters have a smaller bursa of Fabricius and thus lower current levels of immune response than do males with less conspicuous ornamentation. However, males in good physical condition had a relatively small bursa of Fabricius. Furthermore, in *Plasmodium*-infected lizards infected males have lower levels of plasma testosterone and higher levels of the stress hormone corticosterone. However, when the plasma corticosterone level in uninfected lizards was experimentally raised, the animals showed decreases in testosterone level and other accompanying pathological features as are found in infected males in the wild. All these morphological and physiological findings support the idea that only individuals in good health, such as uninfected ones, can afford the handicap of raised androgen levels.

Male's Choice

Since the selection of females by males is less common than vice versa, the existing mechanisms signaling the health of females are little investigated. In pipefish (*Syngnathus typhle*) males are the choosy sex. They were shown to differentiate between uninfected females and those infected by metacercariae of ► *Cryptocotyle* sp., which

induces visible black spots in the skin of the fish. Since there was also a negative correlation between parasite load and female ► **fecundity**, males mating with unparasitized females may benefit directly by fertilizing more eggs. But the importance of the intraspecific assessment of genetic resistance against the parasites should also work in this example. In species with predominantly female mate choice, males were found to be choosy to a certain extent. This was first demonstrated from male laboratory mice showing a preference for uninfected females rather than for those infected with ► *Trichinella spiralis*. But the apparent preference was interpreted in relation to parasite-induced changes in female ability for conception. It was also reported that male mice can discriminate between the odors of nonparasitized females and those infected by *Heligmosomoides polygyrus*, and that they find the odors of parasitized estrous females aversive. Meanwhile, we also know about male birds performing similar discriminations.

Sexual Mate Choice by Infected Hosts

The evolution of mating systems useful in the search for good genes should not only consider the parasite load of the mate being selected but also the parasite burden of the choosy mate, whether this is a male or a female. So far models of parasite-mediated sexual selection have neglected the potential effects of parasites on the ability of their hosts to choose mates. The reports on this subject that are available show that infected mates are less choosy compared to their conspecifics which is often combined with an impairment of other mating behaviors. Thus, behavioral changes of infected hosts may be pathological side effects of infection. Due to an alteration in energy metabolism or hormone levels, for instance, one should always expect an impact on mating behavior. The reduced courtship and territorial behavior (combined with smaller testes and lowered plasma testosterone levels) as shown for instance by male fence lizards infected with *P. mexicanum* should lead to less success in the choice of mate on the part of the infected hosts and

thus work as a driving force in the evolutionary arms race between parasites and their hosts.

Parasite Mating Behaviors

Since the mating systems of the hosts and apparently even sex itself are parasite-driven, one might expect that parasites also show heritable variation in their adaptation to their hosts and that they compete for sexual mates with good genes useful for a parasitic life style.

This seems to be true but so far it is difficult or too early to recognize patterns other than general preference for mates with a high reproductive potential. In the copepod *Lernaeocera branchialis* on flounders male mate choice has been studied. It depended on the sex ratios of the parasite on its hosts and on the age and mating status of females. At most sex ratios, males preferred the stages ► **chalmus** 4 and virgin adult females. Mated females were less attractive but were chosen more frequently at strong male-biased sex ratios.

From schistosomes three findings were described: the existence of a specific male mate preference system, the existence of mating competition and the possibility of change of mate. The principal factor in male mate preference is female fecundity. Thus, paired males prefer remaining with developed and fecund females rather than changing to young immature females. Change of mate does occur when a heterospecific female (in mixed infections) can be exchanged for a conspecific female. When there is a surplus of females, the male is faithful and stays with its reproducing mate and arriving virgins do not become fertilized. However, in infections with a greater number of males compared to females, competitive male mate choice does seem to occur, i.e., unpaired males seem to compete for females.

Meanwhile, parasite mating behaviors are known from several additional host–parasite associations. The general pattern is male–male mating competition for females having a high fecundity potential. Females do not seem to play an active role in mate choice. In acanthocephalans female

worms do not even possess a genital ganglion. Following copulation they become locked by a copulatory cap imposed on their vagina by male excretion preventing further fertilizations until the eggs are discharged. Interestingly, inferior (smaller) males were also found to carry copulatory caps deriving from superior males (“Selfish Gene Hypothesis”). Furthermore, the size of the male testes is modulated by the quantitative presence of mates and competitors. In female-biased infrapopulations the testes are small. In contrast, under competition by a surplus of males worms make the largest testes, probably reflecting upregulation of sperm production.

Data are also available from hermaphrodites with mixed mating systems. Among tapeworms, for instance, partners can modify their rate of cross-fertilization over selfing according to the fecundity potential of the partner. It was shown for *Schistocephalus solidus* that outcrossed offspring achieved both a higher infection success and a higher weight in the copepod, and a higher number of parasites per host in both intermediate hosts (copepod, stickleback), but only under competition. Accordingly, a general preference for cross-fertilization over selfing is practiced but the genetic benefits from outcrossing do not necessarily outweigh the costs of mating with a relatively small individual which has a low fecundity prospect. Furthermore, there seems to be a conflict over who is allowed to give how much sperm, since the opportunity to fertilize a partner’s eggs is more attractive in terms of saving energy than getting their own eggs fertilized.

Behavioral Manipulations

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Many parasites have developed behavioral peculiarities and/or excretions, which allow to change the behavior of their hosts in a way so that their transmission from host to host is strongly supported. Thus there exist psychoneuro-immunological, neuropharmacological, genomic, and proteomic-based mechanisms. Examples are

1. Cercariae of the trematodes ► *Dicrocoelium dendriticum*, which enter the ganglions of ants leading to the fact that they stay overnight outside of their stock (attached at plant leaf), so that they can be ingested by the final hosts (sheep) in the early morning.
2. Hymenopteres of the family Braconidae which introduce their eggs into different arthropods that stop any own activity.
3. Sporocysts of some trematodes (e.g., *Leucochloridium* sp.) enter the head tentacles of their intermediate hosts (snails) and induce heavy movement, so that these snails become an easy prey for the final hosts (birds), where the adult worm is finally formed.

4. *Toxoplasma gondii* is able to change the transcriptome of an infected host by up- or downregulation of several genes. Thus infected mice may become unable to smell approaching cats, which are the final host of ► *Toxoplasma gondii*.

Behring, Emil Adolf von (1854–1917)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Emil Adolf von Behring was a German physician who became a physiologist. He worked until 1893 in Berlin together with coworkers of Robert Koch (Kitasato, Ehrlich) and the famous French scientist Emile Roux in the field of antitoxins against the agents of diphtheria and tetanus (Behring and Ehrlich 1883; Behring and Kitasato 1890; Kantha 1991; Grundbacher 1992). This was a breakthrough, which was honored in 1901 by the award of the first Nobel Prize for Medicine or Physiology and by obtaining from the German Emperor the noble attribute “von” before his family name. He created in Marburg (Germany) the so-called Behring-Werke, which had been for a long time one of the world’s most important producers of vaccines and similar products. Paul ► Ehrlich, who apparently contributed a lot to the honored research work on diphtheria, claimed until the end of his life to be cheated by Behring. Anyway, both are heroes in research, being awarded both with the Nobel Prize for Medicine (Behring 1901, Paul Ehrlich 1908). The importance of this finding shows the history: The Behring/Ehrlich anti-diphtheria toxin was first used

Behring, Emil Adolf von (1854–1917), Fig. 1 Emil A. von Behring, the Nobel Prize winner for Medicine (1901) and founder of the Behring Company for vaccines in Marburg, Germany, in his late years

on Christmas Eve in 1891. Already in 1892, the mortality due to children’s diphtheria dropped in Berlin’s children hospitals from 48 % to 13 %! Nevertheless, it should not be forgotten that both ► Ehrlich and ► Kitasato were congenial coworkers and that Behring alone got the Nobel Prize, although Kitasato was also on list of proposed persons (Fig. 1).

Bertiella Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This genus of cyclophyllidean tapeworms (family Anoplocephalidae) comprises 29 species. Two of

them (*B. studeri*, *B. mucronata*) had been shown to be able to infect humans (especially children) besides their regular hosts monkeys. All cases of infected children showed the typical about 1 cm wide, white proglottids, which contained the typical spherical eggs (50–65 $\mu\text{m} \times 30\text{--}45 \mu\text{m}$) containing the oncosphaera larva (15–19 μm being provided with 6–8 slender hooks of 7–9 μm length). **Transmission** occurs by oral uptake of oribatid mites containing the cysticer-coid larva. **Therapy:** Praziquantel. See ► [Cestodocidal drugs](#).

Besnoitia Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

C. Besnoit = French veterinarian, Toulouse (around 1900).

Geographic Distribution/Epidemiology

Worldwide: in Europe, *B. besnoiti* in Bavaria, France, Spain, and Portugal; in Africa, Israel, Southwest Asia, and China.

Morphology/Life Cycle

There are described several hosts bearing typical cysts in their skin (Figs. 1, 2, 3, 4, 5, and 6; Table 1) and in their conjunctiva of the eyes. The cysts, which represent enlarged host cells with hypertrophied nuclei, reach diameters of 600–800 μm , appear whitish, and can be seen with the naked eye. These cysts are enclosed by 50–100 μm thick layers consisting of connective tissue material and defense cells of the host. Inside the cyst thousands of cystozoites (= cyst merozoites) are enclosed, which reach a size of 9 μm $\times$ 1.5 μm and are constantly reproduced by ► [endodyogeny](#).

Symptoms of Disease of *B. besnoiti*

- (a) **Acute phase:** swelling of lymph nodes occurs prior to the formation of typical cysts; furthermore edema, disturbances of movement, fever, reduction of feeding, etc. are found.
- (b) **Chronic phase:** loss of hair at infected regions of the skin, formation of eczema, weight loss, male sterility, etc. Heavy infections lead to the so-called elephant skin of cattle (Figs. 2, 3).

Besnoitia Species,

Fig. 1 *Besnoitia besnoiti*, section through a cyst of *B. besnoiti* in the skin of a cow. Note that the host cell has developed several enlarged nuclei (blue) and is widely surrounded by a thick layer of filamentous material forming a “secondary cyst wall”

CT connective tissue, HC host cell, NH nucleus of host cell, P parasites within the parasitophorous vacuole

Besnoitia Species, Fig. 5 Transmission electron micrographs of sections through a *Besnoitia besnoiti* cyst. The upper figure shows the remnants of the host cell (HC) with one secondary cyst wall (SW). Both lower figures show sections through cyst merozoites, which are cut longitudinally (*left*) or shown in cross section (*right*). C conoid, ER

endoplasmic reticulum, GS ground substance, HC host cell, M membrane of parasitophorous vacuole, MN micronemes, MP micropore, N nucleus, NH nucleus of host cell, PE pellicle, P parasite, ST subpellicular microtubules, SW secondary cyst wall

Diagnosis

Inspection of the skin and search for tissue cysts in the subcutaneous tissues, microscopically inspection of skin biopsies and serological tests (IFAT).

Infection

Unknown; however, it is supposed that infection occurs by oral uptake of oocysts that had been excreted by meat-feeding final hosts, as had been shown in *B. darlingi*, *B. oryctofelis*, or *B. wallacei*

Besnoitia Species, Fig. 6 *Besnoitia besnoiti*. TEM micrographs of a longitudinal and a cross section through cyst merozoites at different levels. *A* amylopectin granules, *AP* apicoplast, *C* conoid, *DB* dense body, *EN* of

rhoptries, *MN* micronemes, *MP* micropore, *NM* nuclear membrane, *PE* pellicle, *RM* rhoptries, *ST* subpellicular microtubule

(Table 1). However, it is suggested that body contacts of flies may lead to the transfer of cystozoites from wounds of an infected animal to an uninfected one.

Prophylaxis

Doubtful, since the mode of infection is still unclear for many species.

Incubation Period

About 14 days (in experiments obtained).

Prepatency

Less than 2 weeks: supposed.

Besnoitia Species, Table 1 Important *Besnoitia* species

Species	Intermediate host with tissue cysts	Final hosts	Size of oocysts (µm)	Pathogenicity (+/–)
<i>B. besnoiti</i>	Cattle, rodents?	Predator birds?	?	+
<i>B. caprae</i>	Goats	?	?	+
<i>B. darlingi</i>	Opossums, lizards	Cats	11–13 × 10–13	—
<i>B. jellisoni</i>	Rodents, mice	?	?	+
<i>B. wallacei</i>	Rodents, rats	Cats	16–19 × 10–13	—

Bilharz, Theodor (1825–1862)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

He studied zoology and human medicine at the universities of Freiburg and Tübingen (Germany). During his leave at the medical school Kasr-el-Aim in Cairo (Egypt), he described in 1853, as a young MD, the adult schistosomes and their eggs in the blood vessels of the ureter and bladder of patients and animals. The German chief of Bilharz (Prof. von Siebold) published the results (1852) under the name of Bilharz and called the worms *Distomus haematobium* (due to the existence of two suckers at the anterior end of the adults). Later on the pathologist Meckel von Hernsbach (1821–1856) established in 1855 the genus name *Bilharzia*, while Weinland (1829–1915) introduced the name *Schistosoma*. However, the genus name *Bilharzia* was kept until 1905, and the disease was named bilharziosis. Although the priority of the name *Bilharzia* is undoubted, the English-based literature uses as genus name *Schistosoma* starting after the First World War. However, today the Theodor Bilharz Research Institute in Cairo (Egypt) remembers the name of the discoverer of this still very important tropical disease.

Biological Mosquito Larval Control

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

The main target of mosquito-control measurements is directed against the larvae which breed in water. There had been proven significant killing effects by the following *Bacillus* species respectively strains:

- *Bacillus thuringensis*,
- *Bacillus thuringensis israelensis*,
- *Bacillus thuringensis kurstaki*,
- *Bacillus thuringensis tenebriosis*,
- *Bacillus sphaericus*.

The efficacy of these bacteria sprayed onto mosquito larvae containing floods is based on their production of protein crystals (so-called delta-endotoxins), which are produced during sporulation of the bacteria and which are highly toxic to the targeted larvae, but absolutely environmentally safe. Example, in Germany more

Bird Malaria

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Birds are worldwide infected with merozoites/schizonts of various ► *Plasmodium* species. In general there are no severe symptoms in infections (e.g., with *P. relictum*, *P. cathemerium*, or *P. elongatum*). Apparently birds and these protozoans have a long history of coexistence. However, in nonadapted hosts (e.g., penguins or birds imported from far away) severe symptoms and death may occur. Vectors are – depending on the *Plasmodium* species – mosquitoes of the genera *Aedes*, *Anopheles*, or *Culex*.

Blackflies

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Simuliidae

Classification

Family of ► [insects](#), order ► [Diptera](#).

General Information

Fossil blackflies are about 170 million years old. Of the approximately 1,600 blackfly species, only about 900 are man-biting species. Only female blackflies suck blood, demoralizing the host by their painful bites. Since the larvae develop only in flowing water, attacks by adults regularly occur there, and after mass attacks by adults, these can even induce panic reactions in herds of cattle.

Blackflies, Fig. 1 Life cycle stages of *Simulium* sp. (a)/(b) Adult female, (c)/(d) larvae seen dorsally and ventrally, and (e)/(f) pupae; A antenna, AU eye anlage, F foot protrusion, FA anlage of the wing, FK filter fan, H hooks, K head, KI gills

Blackflies transmit protozoan blood parasites to birds but are mainly known as vectors of filarial helminths, especially onchocerciasis (► [River Blindness](#)).

Blackflies are holometabolous insects; larvae and pupae live aquatically. Adults are small, stout-bodied, humpbacked ► [Diptera](#) (Figs. 1, 2, 3, and 4). The best identification criteria are little drops of blood on the legs near flowing waters, accompanied by strong itching reactions. Despite the name, many neotropical species are not black but yellow or orange. Especially larvae and pupae can easily be identified, both anchored to

immersed substrate in flowing water, larvae with the end of the abdomen, which has a “coke”-bottle-like appearance, while pupae with the shoe- or slipper-shaped ► [cocoon](#), out of which the spiracular gills emerge.

Distribution

Blackflies are cosmopolitans. They occur in all geographical regions, but only if flowing water is present.

Blackflies, Fig. 2 Macrophoto of an adult stage

Blackflies, Fig. 4 Scanning electron micrograph of the head of an adult male. Note that the compound eyes contain differently sized single eyes

Blackflies, Fig. 3 Scanning electron micrograph of an adult female

Morphology

The adult blackflies are 1.5–4 mm long, having no large scales on wings and a body like many ► [mosquitoes](#). The head is short, possessing well-developed eyes. The 9–12 (mainly 11) segments of the short antennae are cylindrical. The ► [proboscis](#) of the mouthparts is shorter than the

height of the head and consists of the posterior labium enclosing six stylets (labrum, paired mandibles, paired maxillary laciniae, hypopharynx). The food channel is located between the labrum and the mandibles while the salivary channel between the latter and the hypopharynx. The five-segmented maxillary palps are longer than the proboscis, containing a large carbon dioxide-sensory pit organ. Males and females can be separated according to the weaker developed and untoothed mouthparts of males, but much better by the compound eyes which are larger in males, leaving no space between them on the frons. In addition, males possess greatly enlarged upper ommatidia (Figs. 3 and 4).

The wings are short and broadened by a large anal lobe. The first abdominal tergite forms a prominent scale, bordered by fine hairs.

In the elongated larvae, which measure 4–12 mm in the final ► [instar](#), the head capsule is rarely fully sclerotized. The thorax is broader than the anterior abdomen and not sharply separated from it. The abdomen increases in diameter toward the posterior end, giving the larvae a slightly bottle-like appearance. This expansion is more strongly developed in larvae of fast than of slowly flowing waters. The abdomen ends in a ► [proleg](#) (pseudopodium), possessing many minute hooks, by which the larvae anchor to a pad of silk, secreted by salivary glands which run

through the whole body. The thoracic proleg also possesses such hooks. A pair of cephalic fans, covered with a sticky secretion produced by the cibarial glands, is used for filtering food from the water.

The ► **pupa** is protected by a ► **cocoon** and possesses paired thoracic spiracular gills, which act as a gill plastron, i.e., air remains at the ► **cuticle** and the gas exchange occurs at the air-water interface. The pupa anchors within the cocoon by hooks.

Genetics

In natural populations, it is very difficult to recognize the different species. For very similar species, the term “group” is used, e.g., the *Simulium neavei* group, while for sibling species, which cannot be distinguished according to morphological but only by other criteria, the term “complex,” e.g., the *Simulium damnosum* complex. Nonmorphological criteria are offered by the banding pattern of large polytene ► **chromosomes** in the nuclei of the larval salivary gland cells and sometimes of the Malpighian tubules of adults.

Reproduction

Breeding of blackflies in the laboratory is difficult, but possible for some species. Whereas the larval habitat can be established relatively easily, in most species adults do not mate or suck blood.

Meeting of males and females occurs by chance or when females enter a swarm of males, both near breeding places or hosts. Since in males the copulatory organs do not rotate after emergence as in mosquitoes, copulation, i.e., the transfer of a ► **spermatophore**, occurs on the ground. Presumably one copulation is sufficient to inseminate all eggs. Females lay batches of about 200–800 eggs (0.1–0.4 mm long) mainly late in the day and often on just submerging substrates. In most species, females are gonotrophically concordant, i.e., a blood meal is required for the development of each batch of mature eggs, but there are also autogenic species or populations

laying at least the first batch of eggs without a blood meal. The number of blood meals and egg depositions determines the possibility of transmission of disease. The parous state can be determined according to changes in the ovarioles. Usually the gonotrophic cycle is completed within 3–7 days and can be repeated several times since females in nature can live up to 3–4 weeks.

Life Cycle

An adaptation to unfavorable conditions is the diapause or estivation phase of the egg. Hatching occurs after several months in spring or after droughts for up to 2 years. Normally in tropical regions, embryonic development lasts up to 2 days. Also larvae can survive the winter by a production of cryoprotectants to reduce the supercooling point. Larvae develop in every kind of running water, filtering microorganisms from the water, especially bacteria and diatoms. If larvae wish to settle on another place, they spin a silk thread, detach from the pad of silk, and drift downstream. Usually they settle on submerged substrates near the surface of the water, i.e., in a region with high oxygen tension. Short distances are covered in a looping manner detaching and anchoring alternatively with the hooks on the abdominal and thoracic proleg. The total duration of larval development varies greatly since the number of larval instars varies from 6 to 11 instars (commonly 7), even within a species, and since the development is temperature dependent and can be retarded by the winter. In the tropics, larval development lasts from 4 to 10 days. Then the mature larva, which is actually a pharate pupa with the skin of the final larval instar, spins a slipper-shaped cocoon, orientating the open-end downstream. The development of the inactive pupa usually lasts between 3 and 10 days. During the day, adults emerge from the cocoon in an air bubble which brings them to the surface of the water. The whole developmental cycle (egg to egg) can be completed within less than 2 weeks, but up to several months in diapausing species (Fig. 1).

Transmission/Dispersal

Especially females searching for hosts and breeding sites fly long distances (15–35 km in mark-and-recapture investigations), but when assisted by wind, up to 600 km can be covered.

Feeding Behavior and Transmission of Disease

Host odors induce long-range attraction, followed by ► [orientation](#) to the carbon dioxide source and then a visual orientation to the preferred region of the host. Simuliids usually bite during the day near running waters, showing species-specific peak diurnal biting activities and preferences to specific parts of the body of the host. In the Amazon basin 400–500 and in New Zealand up to 1000 blackflies settled to bite a man in 1 h. Usually the blackflies need 3–6 min to engorge their own weight in blood. Simuliids are ► [pool feeders](#), opening capillaries in a depth down to half a millimeter. The blood is pumped directly into the midgut. Sugar liquids are at first directed into the crop for sterilization and then into the midgut (Fig. 5).

Simuliids transmit filarial helminths and – mechanically – ► [myxomatosis virus](#) of rabbits. Onchocerciasis is caused by the filarial

► [helminth](#) ► *Onchocerca volvulus* and is common in tropical Western and Equatorial Africa, South America, and Yemen.

Interaction of Vector and Parasite

When the simuliids suck blood from an infected human, microfilariae of *Onchocerca volvulus* are ingested, which penetrate the ► [peritrophic membranes](#) and the intestinal wall. In the hemocoel, they migrate to the thoracic flight muscles, in which they grow and molt twice within 6–9 days. The infective L3 larvae migrate to the labium. Movements of maxillae and mandibles during piercing of the skin and the increase of temperature by the blood induce the penetration of the L3 via the soft parts of the labium.

Only rarely have effects of the parasite on the vector been investigated. The penetration of the gut wall and of the cuticle before transmission does not seem to induce a strong decrease of longevity. However, immune reactions and reproduction rate are reduced.

Prophylaxis

Since the adults are active outdoors and during the day, only ► [repellents](#) can be applied to clothing. In addition, people should not be near the water during the various local peaks of biting activity.

Control

Insecticides could be used against adults, but such an outdoor use is nearly impracticable. The better way is a control of the larvae. In a major project, the Onchocerciasis Control Program (OCP) in West Africa, ► *Bacillus thuringiensis* H-14 is also used, meanwhile in rotation with six chemical insecticides (phoxim, temephos, pyraclophos, etofenprox, permethrin, carbosulfan). After 14 years of larviciding, some residual foci remain to be treated, and neighboring countries have established a similar program, the African

Blackflies, Fig. 5 Macrophoto of the udder of a cow showing reactions of numerous bites of simuliid flies

Program for Onchocerciasis Control (APOC), using not only larvicides but also the microfilaricide ivermectin for treatment of humans.

In the OCP countries, the human populations are well informed about the transmission of ► *Onchocerca*, but much less so in the APOC region and South America.

Blackhead Disease

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Symptom

The crest appears black – due to the infection with the amoeboid flagellate.

General Information

► *Histomonas meleagridis* is present in many species of turkeys, chicken, or other birds. The motile parasitic stages (Fig. 1) reach a size of 10–30 µm, some appear with one flagellum others without flagellum, as spherical stage or as slightly amoeboid stage. Stages with two nuclei are apparently in the phase of division (Fig. 1, right below). Recently cyst-like stages also had been described (Fig. 2). The (rarely) reported stages with 2–4 flagella are probably not *Histomonas* but due to coinfections with other flagellates.

The mode of infection with *Histomonas* stages is not yet completely clarified. The most reasonable way is the oral uptake of cyst stages, which may develop from the unflagellated or amoeboid stages in the rectum of the hosts. The quick common start of histomoniasis in a group of birds does underlie this possibility. The contamination of the anal region of the birds with trophozoites is, of course, also possible, when birds place

Blackhead Disease,

Fig. 1 Light micrographs and drawings of unflagellated and amoeboid stages, of which one is apparently in division (right below) showing two nuclei

Blackhead Disease,

Fig. 2 Light micrograph of 4 cyst-like stages of *H. meleagridis* found in the feces of infected chicken

themselves on feces of infected birds. The most unlikely way of infection is due to eggs of the nematode *Heterakis gallinae*. In this case, the unicellular parasite has to penetrate actively into the vagina of the female worm and swim against the stream of excreted eggs up to the place where the worm oocytes are not yet fertilized, since later a thick egg wall will hinder any penetration. The reported “4-year infectivity” of *H. gallinae* eggs is probably related to the fact that the fluid of stored eggs were contaminated with cysts of *Histomonas*.

Pathology

Apparently the amoebic stages enter the intestinal wall, reach the liver, and introduce there huge necrosis (Fig. 3) due to repeated binary fissions of the amoebic stages (Fig. 1, right below).

Blackhead Disease, Fig. 3 Liver of an infected turkey showing complete necrosis

Main Clinical Symptoms

Diarrhea, ► [anemia](#), black crest, general weakening, death.

Incubation Period

Two days.

Patent Period

Several months up to lifelong.

Diagnosis

Microscopic determination of trophozoites in fresh feces, occurrence of cysts.

Prophylaxis

Separation of young from older animals.

Therapy

Oral application of different nitroimidazoles (► [Antidiarrhoeal](#) and [Antitrichomoniasis Drugs](#)); however, none is actually officially registered.

Blasticidin S

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This is an antimalarial toxin of the host that is based on an uptake by PSAC mediation (= plasmodial surface anion channel). After uptake, it stops parasite growth by inhibiting protein translation on ribosomes.

Blastocrithidia culicis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *blastos* = bladder; Latin: *culex* = mosquito.

This trypanosomatid species lives in the intestine of mosquitoes. In contrast to other related species of this group (e.g., *Blastocrithidia triatomae*), their flagellum does not contain a ► [paraxial](#) rod in ► [Flagella](#). Thus their flagella show the typical cross section with its $9 \times 2 + 2$ pattern of microtubuli.

Blastocrithidia triatomae

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *blastos* = germ; Latin: *triatoma* = genus
name of raptor bugs.

Life Cycle

This species belongs to the flagellates and lives in the intestine of raptor bugs (e.g., *Triatoma infestans*), which are the vectors of the agents of the ► [Chagas disease](#) (► *Trypanosoma cruzi*). The life cycle of *B. triatomae* is diagrammatically depicted in Fig. 1. This life cycle contains cyst stages besides amastigotes (micromastigotes), promastigotes, and epimastigotes. The latter are characteristic for the trypanosomatid genus *Crithidia*, which contains members of parasites of insects. This species is able to form cysts, which enable these

Blastocrithidia triatomae, Fig. 1 *B. triatomae*. Life cycle of *Blastocrithidia triatomae* inside its host (the reduviid bug ► *Triatoma infestans*, which may be a vector of *Trypanosoma cruzi* too). 1 The bug ingests feces containing cysts. 2 Excystation inside the midgut within 12–48 h after uptake. 3–5.1 Development (by ► [binary fission](#)) of pro-, epi- and spheromastigotes inside the whole gut. 6, 7 ► [Encystation](#) inside the rectum (6 days

p.i.). After unequal binary divisions, the smaller daughter cell remains attached to the flagellum of the other cells and encysts. The cysts are often attached “straphanger-like” along the flagellum of nonencysted flagellates. After 14–21 days, infectious cysts are excreted within the feces of the bug. B basal body, CM cyst wall, F flagellum, KI ► [kinetoplast](#), N nucleus

***Blastocrithidia triatomae*, Fig. 2** (a–e) Cyst formation with increasing (a, e) desiccation in *Blastocrithidia triatomae* (see life cycle). Note that the nucleus has a labyrinthine pattern (LS). The cyst wall consists of a dense layer (DL) below the ► cell membrane (OM). Cysts (d) are attached (straphanger-like) to the ► flagella

of mastigote stages (e). (a, b, c $\times 22,000$; d $\times 33,000$; e $\times 2,000$). DL dense layer, F flagellum, G large granules, K ► kinetoplast, LS labyrinthine structure of the nucleus, OM cell membrane, S straphanger-like cysts, ST ► subpellicular microtubules, V vacuole

stages to survive outside their hosts. For human medicine, it is important that exclusively *Blastocystis* free bugs must be used for ► xenodiagnosis of ► *Trypanosoma cruzi* infections. Otherwise wrong positive results would be obtained.

Blastocystis hominis

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name

Greek: *blastos* = bladder; *kystis* = cyst; Latin: *homo* = human.

Geographic Distribution/Epidemiology

Worldwide; up to 20 % prevalence rates in healthy people, extremely high rates in AIDS patients (up to 50 %).

Morphology/Life Cycle

Blastocystis was first thought to be a fungus (nonpathogenic yeast), but it is now recognized as parasitic protozoan organism inhabiting the cecum and large intestine of humans and animals. Morphology of *Blastocystis* isolates has been extensively elucidated by light microscopy using the samples from fresh fecal materials and axenic or xenic cultures of human and animal isolates. *Blastocystis* is strictly an anaerobic eukaryotic unicellular organism, because the cells are quickly degenerated when they are exposed to the air. The most typical feature of this organism is its polymorphic appearance, including a great variation in cell size and distribution of granules in the large central vacuole and occurrence of polymorphic morphological shapes from spherical to amoebic forms. Polymorphic stages are frequently observed not only within a single sample but also among isolates in fresh materials and in vitro cultures. Therefore, it is difficult to assign a standard morphology for diagnosis of clinical samples.

Although *Blastocystis* organisms have been isolated from a variety of animals including mammals, birds, reptiles, amphibians, and insects, all isolates are morphologically indistinguishable. However, there are various terms for morphologically different *Blastocystis* organisms that appear in human and animal fecal samples based on the light microscopy. Namely, there are vacuolar (vacuolated), multivacuolar, avacuolar, granular, amoeboid (ameba), and cyst forms. In general, the vacuolar and granular forms are the most predominant in the fresh fecal and in vitro culture samples. The amoeboid form is generally more frequently observed in the samples of in vitro cultures than in fecal materials, while

Blastocystis hominis, Fig. 1 Light and transmission electron microscopic photo of a vacuolar stage of *Blastocystis hominis* from diarrheal stool (arrow points on a nucleus)

predominant excretion of the amoeboid form in stool samples of symptomatic patients has been recently reported. Irregular shape of the amoeboid form is difficult to be distinguished from the amoebic forms of other intestinal protozoans, and locomotion of the amoeboid form of *Blastocystis* has not been recognized. The cyst form is mainly seen in the stool samples and is rare in vitro cultures. The cyst form is relatively small in size, 3–5 μm in diameter; hence it is difficult to identify it in the fecal samples by routine diagnostic examinations. Several cyst-concentration techniques to detect cysts from fresh fecal samples have been reported. The vacuolar and granular forms are generally round in shape and range in size from about 5–50 μm in fecal samples. When the organism is cultured, it can grow to a size of more than 50 μm and may reach up more than 200 μm in diameter. Under phase contrast and Nomarski differential interference microscopy, a large central vacuole can be clearly observed in the center of the organism. The cells having an empty vacuole are called vacuolar forms (Figs. 1, 2). The function of the central vacuole is not yet fully confirmed. However, metabolic and storage functions of the central vacuole

containing various substances such as carbohydrates and lipids have been demonstrated by light microscopy. Since the central vacuole occupies more than 80 % of the cell volume, the cytoplasm of the organism is pushed to the periphery and is lined thinly just under the cell membrane. During in vitro culture and also in fecal samples, some take the shape of a peanut, which indicates that the organism is in the process of cell division. Many small-sized or a mass of granules are sometimes observed in the central vacuole in fecal samples and cultures, and this stage is called the granular form. Granular forms in the process of binary fission can also be observed (Fig. 2).

Symptoms of Disease (Blastocystosis)

The pathogenicity of *B. hominis* is under discussion. However, this protozoon is often found as single present organisms in cases, where people suffer from slimy diarrheas, abdominal pain, nausea, inappetence. In addition, single cases had been reported, where bloody dysentery occurred. As main symptom (especially in immunocompromised people) strong watery diarrheas (up to 8 liter per day) were reported.

Diagnosis

Microscopical demonstration of trophozoites/cysts in stools after use of concentration methods such as M.I.F.C., S.A.F.C., flotation (Fig. 1).

Infection

Probable oral uptake of cyst-like stages from stool of other persons. It was proven in experiments with animals that cysts derived from humans are also infectious for pigs. Thus it must be concluded that there is no strict host specificity, which leads to a possible wide natural spreading.

***Blastocystis hominis*,**

Fig. 2 Diagrammatic representation of the potential life cycle of *B. hominis* (according to results of Yoshikawa, Tan, and several other authors. *N* nucleus, *V* vacuole

Prophylaxis

Avoidance of contact to human or animal feces (especially in the case of AIDS patients).

Patency

Two to three weeks.

Incubation Period

In the case of humans: unknown; in animals: 2–3 days.

Prepatent Period

Two to three days.

Treatment

In the cases of relevant symptoms of disease and in absence of symptoms due to other parasites or bacterial infections, treatment was successful with metronidazole (3 × 700 mg or 4 × 500 mg daily for 5–7 days). Cotrimazol was as well effective (2 × daily 160 mg trimethoprim/ 800 mg sulfa-methoxazole. Children: 6–30 mg/kg bodyweight for 7–10 days). However, for both medicaments, failures of treatment have been reported too.

Introduction

The vast majority of cockroaches live in the tropics and subtropics, are nocturnal, and hide during the day in the soil and under loose bark, wood, or stones. With their dorsoventrally flattened body and their light to dark brown color, cockroaches are highly adapted to the hidden life in the underground. Most of the species play an important beneficial role in the tropical and subtropical ecosystems with an exception of only a few domiciliary pests with worldwide distribution.

Appearance

The representatives of the order Blattaria (class, Insecta; superorder, Dictyoptera) have a dorsoventrally flattened body. The shield-like pronotum overlaps the head. The tegmina (forewings) are leathery and merged in resting position flat over the abdomen. The delicate and hyaline hind wings are usually fan shaped folded below the forewings. They are atrophied or absent in many species. The adults of many species of cockroaches have significant gender differences. In many species, the males are equipped with a slim body and fully developed tegmina and hind wings, while the females have a stocky body shape with short or rudimentary tegmina and without hind wings.

The head carries long, filiform antennae with many segments, chewing mouth parts with strong and toothed mandibles and usually large, flat compound eyes. Only small cave-dwelling species

have reduced eyes or the eyes are completely absent.

Both sexes carry two long cerci at the end of the abdomen and the males have additionally two styli. The usually slender and strong legs are occupied with spines and allow fast running and even small jumps. Arolia on the tarsal segments allow many cockroach species even to run or to land on vertical, smooth surfaces. Many species have additionally euplantae between the claws which facilitate adhesion to the underground during locomotion even on smooth walls and ceilings. The body length of cockroaches is between 3 mm (genus *Nocticola*) and 85 mm (*Macropanesthia rhinoceros*) (Roth 1991; Bell et al. 2007).

Systematics

The order Blattaria was already widespread in the Upper Carboniferous 280–330 million years ago, and the species have changed little since that time. They are systematically related to the Mantodea in the superorder Dictyoptera (Table 1). While the Manoidea evolved into highly specialized predators, cockroaches remained until now with their original hidden life (Beier 1974; Bell et al. 2007; Cochran 1999; Cornwell 1968; Roth 1991). More than 3,500 species of cockroaches have been reported worldwide so far, which are divided into six families. Several authors assume that the number of Blattaria species worldwide may now exceed more than 6,000 species (Bell et al. 2007).

Accidental Introduction

Cockroaches accompany humans as pests, since they began to settle down and to build up stocks.

Their nocturnal activity and preference for dark and narrow hiding places in the leaf litter and ground-level vegetation, its broad food spectrum, and low specialization enable cockroach species to take advantage of the human environment as a habitat and food source (Beier 1974).

With increasing trade in the Middle Ages, cockroaches were displaced from their origin in the tropical areas with sailing ships from continent to continent, so that the origin of synanthropic species cannot be determined with certainty today. Various *Periplaneta* species reached North America from West Africa at the beginning of the seventeenth century (Barcay 2004).

Cockroaches were also deported by ship traffic to European harbors. However, up to the middle of the twentieth century, only a few species could establish permanently in Europe. Due to the reinforced and accelerated movement of goods, the increasing urbanization, and the changing living conditions of the population, the conditions for imported species of cockroaches in the last 40 years have improved. Large livestock farms, industrial food processing, and modern heating systems, especially district heating, provide constant temperature conditions in the winter months, which allow also tropical species to establish in Central Europe (Pospischil 2010).

Until 1900, only two synanthropic cockroach species were of importance as pests in Central Europe, the German cockroach *Blattella germanica* and the Oriental cockroach *Blatta orientalis*. The Australian cockroach *Periplaneta australasiae* was reported from tropical greenhouses since the beginning of the twentieth century. This picture changed in the second half of the twentieth century. Ten species are now described to survive under Central European conditions in buildings (Table 2).

Blattaria, Overview, Table 1 Systematical classification

Superorder	Dictyoptera			
Order	Mantodea (Fangschrecken)	Blattaria (Schaben)		
Superfamily		Polyphagoidea	Blattodea	Blaberoidea
Family		Polyphagidae Nocticolidae	Blattidae Cryptocercidae Termitidae	Blattellidae Blaberidae

Blattaria, Overview, Table 2 Synanthropic cockroach species in Central Europe

Common name	Scientific name	Family
German cockroach	<i>Blattella germanica</i>	Blattellidae
Brown banded cockroach	<i>Supella longipalpa</i>	Blattellidae
Oriental cockroach	<i>Blatta orientalis</i>	Blattidae
Turkestan cockroach	<i>Shelfordella lateralis</i>	Blattidae
American cockroach	<i>Periplaneta americana</i>	Blattidae
Australian cockroach	<i>Periplaneta australasiae</i>	Blattidae
Brown cockroach	<i>Periplaneta brunnea</i>	Blattidae
Harlequin Cockroach	<i>Neostylopyga rhombifolia</i>	Blattidae
Surinam cockroach	<i>Pycnoscelus surinamensis</i>	Blaberidae
Argentinian wood cockroach	<i>Blaptica dubia</i>	Blaberidae

Transmission of Pathogens

Synanthropic cockroach species feed on practically all organic materials that have a nutritional value, in which dustbins, garbage disposals, disposal wells, and sanitary facilities have a special attraction. There, cockroaches can easily become contaminated with pathogens.

The potential of cockroaches to transmit diseases in the human environment is well documented especially in the North American literature (Auer et al. 1994; Benson and Zungoli 1997; Brenner 1995; Cochran 1999; Olson and Rueger 1950; Stek et al. 1979 and others). More than 32 human pathogenic bacteria species, various pathogenic protozoa, eggs from seven tape-worm and nematode species, spores of different fungal species, and two types of virus were found on the cuticle and in the intestine of synanthropic cockroaches (Benson and Zungoli 1997; Brenner 1995; Cochran 1999) (Table 3). These pathogens can be transmitted mechanically by attachment to the cuticle or through ingestion and subsequent excretion in excrements or regurgitated crop content. The crop content is particularly problematic, because a mass proliferation of microorganisms

Blattaria, Overview, Table 3 Pathogens found on the cuticle and in the crop of cockroaches (Benson and Zungoli 1997)

Group	Human pathogen
Bacteria	<i>Alcaligenes faecalis</i> , <i>Bacillus subtilis</i> , <i>Campylobacter jejuni</i> , <i>Clostridium perfringens</i> , <i>C. novii</i> , <i>Enterobacter aerogenes</i> , <i>Escherichia coli</i> (different strains), <i>Klebsiella pneumoniae</i> , <i>Listeria monocytogenes</i> , <i>Nocardia</i> spp., <i>Pseudomonas aeruginosa</i> , <i>Proteus mirabilis</i> , <i>P. vulgaris</i> , <i>P. rettgeri</i> , <i>P.morganii</i> , <i>Pseudomonas aeruginosa</i> , <i>Salmonella typhimurium</i> , <i>S. bareilly</i> , <i>S. bredeney</i> , <i>S. enterica</i> , <i>S. enteritidis</i> , <i>S. newport</i> , <i>S. oranienburg</i> , <i>S. panama</i> , <i>S. bovismorbificans</i> , <i>S. paratyphi B</i> , <i>Serratia marcescens</i> , <i>Shigella dysenteriae</i> , <i>Staphylococcus aureus</i> , <i>Streptococcus faecalis</i> , <i>S. pyogenes</i> , <i>Vibrio</i> spp.
Fungae	<i>Alternaria</i> sp., <i>Aspergillus niger</i> , <i>A. flavus</i> , <i>A. fumigatus</i> , <i>Candida albicans</i> , <i>C. krusei</i> , <i>C. parapsilosis</i> , <i>C. tropicalis</i> , <i>Cladosporium</i> sp., <i>Fusarium</i> sp., <i>Geotrichum candidum</i> , <i>Mucor</i> sp., <i>Penicillium</i> sp., <i>Trichoderma viride</i> , <i>Trichophyton rubrum</i> , <i>Trichosporon cutaneum</i>

can take place over up to several weeks. Bacteria of the genus *Salmonella* can remain virulent up to 6 weeks in the digestive tract of *Blatta orientalis* (Olson and Rueger 1950), in the digestive tract of *Blattella germanica* up to 9 days (Janssen and Wedberg 1952), and on the cuticle of *Blattella germanica* at least 10 days (Graffar and Mertens 1950). Stek et al. (1979) demonstrated that cockroaches can accommodate species of the bacteria genera *Klebsiella*, *Proteus*, *Shigella*, and *Salmonella* in their digestive system.

Direct evidence of transmission of certain pathogenic bacteria of cockroaches to humans or domestic animals is difficult to perform, since the transfer is done usually indirectly via contaminated food or on devices that are needed for the preparation of food (Brenner 1995).

The importance of *Blattella germanica* in the distribution of antibiotic-resistant *Salmonella* strains from pig houses to surrounding residential

buildings was described by Zurek and Schal (2004). Comparable results were obtained from studies of Fathpour et al. (2003) on *Blattella germanica*, *Periplaneta americana*, and *Supella longipalpa* in hospitals, homes, and poultry facilities in Iran. Seventy percent of the examined cockroaches were contaminated with *Salmonella* spp., of which a high percentage was antibiotic resistant. Fuchs (1976) isolated 29 pathogenic fungal species of the cuticle as well as from the digestive tract of *Blattella germanica* populations that were collected from kitchen companies (including species of the genera *Aspergillus*, *Fusarium*, *Penicillium*, and *Alternaria*).

Allergic Reactions to Cockroaches

Allergies strongly increased in industrialized countries in recent decades. Within the building, the so-called house dust allergy has increased dramatically, which is caused to a high extent by house dust mites, fungi, and synanthropic cockroaches. The importance of cockroach allergens, especially in the urban areas, has been studied intensively since 1990. It was found that cockroaches, in particular *Blattella germanica*, are heavily involved in the so-called house dust allergy in inner cities and exceed in their allergenic potency even the dust mites (Stewart and Thompson 1996; Rosenstreich et al. 1997). It was found in large-scale studies in seven inner cities of the United States with 1,500 4–11-year-old children over a period of 12 months that three times as many children suffered in the urban areas with asthma as in the suburbs (Rosenstreich et al. 1997). These results could be confirmed by numerous other studies worldwide (Sastre et al. 1996; El-Gamal et al. 1995; Onoue et al. 1995; De Blay et al. 1997; Peruzzi et al. 1999).

Causes for the increase in allergies are differences in the living environment and the behavior of people during the last 50 years. Especially in the inner cities, many people spend more than 90 % of their time indoors (home, workplace, restaurants, etc.) and are thus longer exposed to the allergens. Central heating systems provide a

favorable climate for cockroaches and improved thermal insulation and shorter ventilation periods, and the increasing use of air conditioning systems provoke an increase of the allergen load in the air (Rosenstreich et al. 1997).

Allergic reactions manifest in an irritation of the mucous membranes in the nose and eyes. Progressive sensitization leads to bronchial responses and to asthmatic attacks. The allergenic reaction of exposed persons depends on the genetic susceptibility of individuals to allergens, the strength of the cockroach infestation, the duration of exposure, and the cockroach allergen exposure through air conditioning, ventilation, etc.

Proteins Causing Allergic Reactions

The allergens can be released from the blade on the crop content, parts of the cuticle, pheromones, and excrements, wherein different protein fractions are responsible for the allergenic potency with a molecular weight between 10 and 50 k Dalton. Eight to 13 proteins were found to be responsible for the allergic potential of *Blattella germanica* (Table 4). Cross-reactions with other species of cockroaches (*Blatta orientalis* and *Periplaneta americana*) were also found. The allergenic acting proteins of the German cockroach were registered as Bla g1 to Bla g7. Bla g2 consists of an aspartate protease with 328 amino acids (molecular weight: 36 k daltons), which is distributed with crop content and excrements in the environment. Bla g5 is homologous to glutathione transferase (Stewart and Thompson 1996; Jeong et al. 2003; Gore and Schal 2005).

One allergenic protein was isolated from *Periplaneta americana* and three from *Blatta orientalis*, respectively. The functions of these proteins of both cockroach species are still unknown (Stewart and Thompson 1996).

These allergenic proteins are widespread in the animal and plant kingdom. Most are metabolic enzymes, whose active sites are responsible for the allergenic potential. Hydrolytic enzymes (proteases, carbohydrases, and ribonucleases) are frequently involved in allergic reactions.

Blattaria, Overview, Table 4 Allergenic proteins from cockroaches (*Blattella germanica*, *Blatta orientalis*, and *Periplaneta americana*) (Jeong et al. 2003; Perez-Santos 1995; Stewart and Thompson 1996)

Source	Designation	Size	Function
<i>B. germanica</i>	Bla g 1	25 k Dalton	Not identified
<i>B. germanica</i>	Bla g 2	36 k Dalton,	Homologous to the aspartate protease
<i>B. germanica</i>	Bla g 3		Not identified
<i>B. germanica</i>	Bla g 4	20 k Dalton	Not identified
<i>B. germanica</i>	Bla g 5		Homologous to the glutathione transferase
<i>B. germanica</i>	Bla g 6		Not identified
<i>B. germanica</i>	Bla g 7		Tropomyosin
<i>P. americana</i>	Per a1	25 k Dalton	Not identified
<i>B. orientalis</i>	–	3 proteins with 40–45 k Dalton	Not identified

Lipogenases, alcohol dehydrogenases, glutathione, and aldolases were detected as allergens for cockroaches and fungi (Perez-Santos 1995; Stewart and Thompson 1996).

Blood-Licking Bats

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Three species of bats (Chiroptera, from Greek *cheir* = hand and *pteron* = wing) are known as so-called vampire bats to attack animals and occasionally humans:

- *Desmodus rotundus* (common vampire)
- *Diphylla ecaudata* (whitewing vampire)
- *Diaemus youngi* (combteethed vampire)

As the other worldwide occurring bats, they are mammals with a constant body temperature of 31 °C, give birth to their progeny, and possess an excellent system of hearing reaching of up to 400 kHz, while the hearing of humans stops already at 21 kHz (Flindt 1986; Hoyt and Altenbach 1981) (Fig. 1).

Blood-Licking Bats, Fig. 1 A “flying fox” from Australia showing its sharp teeth while disturbed

These three blood-engorging bat species have their habitats in warm regions that stretch from Chile/Argentina to Texas and are also found on some islands in the Caribbean Sea. They have a body length of 6–10 cm, but their total wing span may reach the respectable diameter of up to 40 cm, which is impressive when they fly at night with a speed of up to 50 km/h around humans (Flindt 1986; Siewing 1985). Their dorsal fur color is dark brownish, while the belly appears lighter (gray). The hind legs of vampire bats are rather strong compared to other bat species, and thus they are able to walk or jump on the ground when approaching sleeping preys at night and when starting their flights from the ground. The vampire bats prefer special hosts. *Desmodus rotundus* feeds exclusively on mammals and *Diphylla ecaudata* exclusively on birds (Hoyt and Altenbach 1981), while *Diaemus youngi* sucks blood on both types of hosts. Having discovered a sleeping host, the bats land close by on the ground. A direct landing on a host would probably wake up this animal. Therefore, the vampire bats crawl or hop so close to their prey that they are able to bite. By help of temperature receptors around their mouthparts, they start to search for a blood vessel. At first they lick at the selected skin places, whereby the anesthetizing components of the saliva make them numb for the following bite. The bats bite by help of their pointed eyeteeth and their sharp incisors. Thereby, they scratch the skin and thus reach the underlying blood vessels. Their saliva contains as mentioned above anticoagulants that keep the blood liquid (as it is in the case of leeches, too). By help of their grooved tongue, the bats lick the flowing blood until they have engorged around 30 ml. Having finished their meal within less than 2 min, they fly back to their sleeping places in caves of mountains and into mines or barns, or they even settle in rotting large trees. These vampire bats live together in rather small groups of 100 individuals (when, e.g., compared to the hundreds or even thousands of tree-fruit bats in Australia). They have developed social system to help sick, weak, or unsuccessful members of their group. Successful hunters will share their

ingested meal. After arriving at their sleeping places, they vomit – if necessary – some portions of their blood meal to feed weak members of the group.

Molecular biological studies gave hints that the development of blood feeding was only developed once within the group of bats (Tellgren-Roth et al. 2009; Wetterer et al. 2000). These findings are based on the genus-specific activity of a few genes that help to express the anticoagulant components (i.e., so-called plasminogen activators (PAs) – relatives of the group of serine proteases). It has been evaluated that feeding of bird blood is the most ancient way of food uptake, followed by enlarging their food spectrum from birds to mammals and finally reaching exclusivity in *Desmodus rotundus* of feeding on mammals after the genetic development of four different plasminogen activators (PAs) had been successfully developed.

The importance of vampire bites in humans and farm animals is rather high, since it was proven that the vampire's saliva may contain viruses that may introduce severe and possibly fatal diseases. Thus, death toll among humans due to the rabies virus disease is high in rural regions, the homeland of these bats. However, the transmission of other viruses is also possible and needs much more consideration. Since several hundred thousands of cattle are attacked per year, their growth and milk production are considerably reduced, thus leading to large economic losses in these relatively poor countries in South and Central America. Therefore, there are yearly campaigns of eradication of the especially numerous bats of the species *Desmodus rotundus*, which is absolutely not endangered in contrast to many insectivorous bat species.

The mysteries around bats led to the creation of a human bat (i.e., Batman) first in comic books and later in movies (Banhold 2008; Beatty 2002), wherein the enormous flight abilities and the nocturnal activity of true bats are the predominant skills of this mysterious combination of human activity and animal behavior of Batman.

Simplified Nomenclature of Blood-Licking Bats

Classis: Vertebrata

Ordo: Chiroptera

Subordo: Microchiroptera

Family: Desmodontidae (true vampires)

Species: *Desmodus rotundus*

Diphylla ecaudata

Diaemus youngi

Origin of names:

- Chiroptera = bats. The name comes from Greek *cheir* = hand and *pteron* = wing.
- *Desmodus* = Greek *desmos* = band; Latin *modus* = type; *rotundus* = round.
- *Diphylla* = Greek *dis* = double; Greek *phyllon* = leaf; Latin *ecaudata* = without; *caudatus* = with tail.
- *Diaemus* = Greek *di* = two; Latin *aemulus* = imitating; *youngi* = name of a scientist (Young).

Rabies

This disease is based on infections with so-called **lyssaviruses**, which belong to the rhabdovirus group. Among the lyssavirus group, seven different genotypes are described; five of them have their exclusive reservoir in worldwide occurring bats (Chiroptera), while genotype 1 (the “classic” agent of rabies) may also be transmitted by bites of several terrestrial animals (e.g., foxes, dogs, cats). The WHO claims that there are approximately 55,000 human death cases per year alone in Africa and Asia being induced by dog bites, while in Europe “only” 50 persons die caused by such rabies infections. The bullet-like appearing rabies viruses measure 100–300 nm in length with a diameter of 75 nm and contain a helically arranged

(continued)

ribonucleocapsid with about 12,000 nucleotides.

The viruses are present in the saliva of infected animals and thus are transmitted by bites. Just after infection their reproduction starts in the cells of the surrounding tissues and/or in the local nerve endings. The **incubation period** of the disease is rather variable. In 25 % of the cases, the first symptoms start within the first 30 days, while in 50 % of the cases it takes 30–90 days. In the rest of cases, the incubation period may be prolonged considerably.

The **clinical symptoms** are characterized by unspecific symptoms such as vomiting, dizziness, and headache. After this phase neurological symptoms follow. During this rather short period of 2–7 days, the following symptoms are seen: encephalitis, aggressive behavior, aero- and hydrophobia, and the very typical hypersalivation. Death occurs finally due to breakdown of kidneys and of blood circulation.

If an infection and clear symptoms had occurred, there are no more chances for a causative medical cure. However, as long as symptoms have not yet occurred, there is the possibility of a so-called postexposure prophylaxis by help of a tissue cell vaccine (Roß et al. 2009). However, efficacy and healing are not guaranteed. Thus, it is very important that people working in forests or on farms become vaccinated, which is given in three doses regularly on days 0, 7, 21, or 28, so that beginning from day 35 protection is reached. Furthermore, it should be noted that wild animals that try to come into close contact to humans are mostly infected by rabies.

Blue Tongue Disease (BTD)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Ovine catarrhal fever; Pseudo mouth and claw disease

Name

French: *fièvre catarrhale du mouton*; Spanish: *lengua azul*; African: *bloutang*.

This disease occurs in wild and stock ruminants due to infections with ► **BTD** virus that is transmitted in Africa mainly by *Culicoides imicola*, in Central Europe (new) by *C. obsoletus*, in the USA by *C. variipennis*, and in Australia by the *C. schultzei* group.

Symptoms of Disease

Characteristics are the name-giving blue tongue due to cyanosis (rather rare); severe nasal discharge; subcutaneous hyperemia; petechiae; lacrymation; facial, mouth, udder, and lung edema; swollen lymph nodes; and typical foot lesions leading to general stiffness, abortion, torticollis, and death.

Mortality Rate

In sheep, death rate reaches 80 %, 3–5 % in cattle, and very low rates (if at all) occur in wild ruminants.

Bluebottles

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

English trivial term for the metallic blue appearing adults of the genus ► **Calliphora**.

Bluetongue Virus (BTV)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This is a so-called orbivirus within the family *Reoviridae*, which has a size of 70 nm and possesses

double-stranded RNA with about 10–12 genome segments. BTV is transmitted during the bite of the very tiny females of the insect family ► **Ceratopogonidae** (midges). The most important symptom of the disease in ruminants is hemorrhages in the mouth (i.e., leading to a blue tongue), on the surface of the udder and between the claws introducing painful and stiff movements of cattle. The disease which is common but mostly symptomless in South African game animals is based on any 24 different serotypes of this virus. Although the disease is not contagious, it led since its first arrival (1998) in South Europe to the death of more than one million sheep and also many thousands of specimens of cattle.

Since 2006 whole Europe was hit by two virus epidemics in ruminants, which followed each other: bluetongue disease (BTV) in the years 2006–2009 and occurrence of the so-called Schmallenberg virus epidemic (SBV) in 2011–2013 (Mehlhorn et al. 2007, 2009; Wernicke et al. 2013). While BTV introduced extreme mortality rates among adult cattle and sheep, SBV struck mainly the fetus of ruminants. In both epidemics the first cases of infected hosts were found close to the connecting borders of Germany, Belgium, and the Netherlands, from where spreading occurred. As well as in both cases, the vectors were the same: midges of the genus *Culicoides* (e.g., *C. obsoletus*, Fig. 1). After severe losses in cattle and sheep, the bluetongue virus epidemic (due to serotype 8) was finally stopped with the help of a newly produced vaccine. In the case of the Schmallenberg virus, the progress of the epidemic slowed down considerably without the use of the now available vaccination. Since mainly fetal or newborn animals had been hit and since adults showed only slight signs of the disease, apparently the immune system of previously infected adults had been boosted, so that fetal infections were reduced. Both epidemics had their origin in the import of viruses, which have their main distribution in faraway overseas countries. However, several other bluetongue serotypes have already arrived in Europe. For example, serotype BTV-1 is present in France, Spain, and Portugal. In addition serotypes BTV-2, BTV-4, BTV-9, and BTV-16 are already present in several European countries. At the beginning of the epidemics, it was believed

Bluetongue Virus (BTV), Fig. 1 Female *C. obsoletus*

that global warming could be a reason for these outbreaks. However, since it is clear that the vector species (the midges of the genus ► *Culicoides*) inhabit definitively whole Europe, the phenomenon of globalization (e.g., transportation of goods and animals from one end of our world to the other) is probably the main reason for these outbreaks of severe viral diseases in Europe. Other agents of diseases will surely follow on these pathways, an increased northward migration of “southern” species through the English Channel into the North Sea. An anticipated future rise in global temperature is likely to enlarge the geographic distribution of marine as well as freshwater species with a trend toward a broadening of species diversity and productivity.

Prevention: Since vaccines are only available for very few of the 24 serotypes, protection of cattle and sheep in farms should be done by application of insecticides on the hair (e.g., flumethrin, deltamethrin) which protect the animals from vector bites for about 3–4 weeks.

Bodonidae

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Family of unicellular fish parasites. An important example is ► *Ichthyobodo necator* (syn. *Costia necatrix*).

Bodonids

Member of the flagellated protozoan family Bodonidae. *Ichthyobodo* (syn. *Costia*) *necatrix* and *Trypanoplasma borreli* are important fish parasites.

Body Cover

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Integument; Cuticle; Skin

General Information

The parasite-host interface is the place where nutrients are taken up and is the site of the attacks of the host's defense system. In the parasitic ► *Metazoa* considered in this book, two main types of body cover exist:

- An acellular filamentous ► *cuticle* (excreted by an underlying cellularly organized hypodermis) is found, e.g., in ► *nematodes*,

pentastomids, and in arthropods (► [Ticks](#), ► [Mites](#), ► [Insects](#)).

- A syncytial cytoplasmic ► [tegument](#), where giant nuclei or nuclear fragments may occur, covers the surface of larval monogeneans, digeneans, ► [cestodes](#) and ► [acanthocephalans](#), whereas the tegument (i.e., neodermis = new skin) of adult parasitic platyhelminths lacks nuclei (► [Platyhelminthes](#), Figs. 11 and 12).

The surface of both types of outer body cover (cuticle or tegument) may be lined by more or less thick layer(s) of carbohydrates, mucopolysaccharides, or even membranous material depending on the species and the site of parasitism.

The ► [surface coat](#), which fulfills its tasks in defense against environmental influences while covering “normal” and parasitic cells, is thought to be the ancestor of all cuticular systems (► [Cuticle](#)) of the whole animal and plant world. Apparently during evolution, the ► [glycocalyx](#) while situated between body and/or cell protrusions (e.g., ► [microvilli](#), protuberances) became fortified by enclosure of fibers of collagen, ► [chitin](#), cellulose, and/or calcium carbonate components, etc. Thus, the original protection system received a second function, i.e., the preservation of the body shape as system belonging to the exoskeleton. However, the uptake of nutrients through this increasing outer surface remained possible using a variety of mechanisms and carrier systems (► [Membrane Transport](#); ► [Endocytosis](#)). Thus, for example, schistosomes are able to take in huge amounts of glucose through their surface membranes, and ► [nematodes](#) may also become hidden by several drugs as a result of cuticular uptake.

host. This host offers food to parasitic stages during their development inside its body and later protects these parasites even after they have left its body from attacks of free-living predators. This type of parasitic manipulation is mainly described from ► [parasitoids](#) (like wasps), which spent part time of their juvenile development inside caterpillars, which later defend by help of threatening body movements the pupal stages of the wasps after the larvae had left its body.

Boophilus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *bos* = cattle, *philein* = loving.

General Information

Genus of hard ► [ticks](#) (Fig. 1) of ruminants (wild and farm). The species apparently originated from Africa, however, are now spread all over the world. Most important species are *B. microplus*, *B. decoloratus*, and *B. annulatus*. They are one-host ticks, which need only about 3 weeks until the females drop down to floor. Five days later the females depone about 2000–4500 eggs, which need about 3–6 weeks (temperature dependent) until the larvae hatch. The period of egg deposition can be stretched up to 120 days. The larvae may starve without host for 90 days (summer) or up to 180 days (winter). Due to their life cycle *Boophilus* sp. mainly transmit

Boophilus, Fig. 1 *Boophilus microplus*. Engorged females of this one-host cattle tick species laying eggs. This species is found in Australia, Asia, Latin America, and East Africa. The development on cattle needs 3 weeks; egg excretion (on the soil) takes 1–2 weeks. Thus 5–6 generations develop per year and may transmit ► [Babesia](#) parasites of cattle. The name comes from Latin *bos* = ox, cow and Greek *philein* = friend, loving

agents of disease, which enter the eggs of the ticks (e.g., viruses, ► [Babesia](#), [Anaplasma](#)).

Boophilus: Prevention and Control

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

1. *B. annulatus* (so-called American cattle tick) occurs in Mexico and in some regions of Africa. It was eradicated from the USA.
2. *B. decoloratus* (so called Tropical cattle tick or Blue tick) occurs in regions of Central, East, and Southern Africa.
3. *B. microplus* (so-called Southern cattle tick) occurs in Latin America, Australia, Southeast Asia, and East and West Africa after being eradicated from the USA.

All these so-called **one-host ticks** are very important vectors of diseases of the animals of livestock,

since they may transmit different ► *Babesia* species (*B. bovis*, *B. bigemina*, *B. divergens*) and in addition *Anaplasma marginale*, *A. centrale* as well as *Borrelia theileri*) which all may be fatal for cattle. Even if there is no transmission of any agent of disease, the blood loss due to blood sucking of ticks may be enormous. E.g. it is calculated that only 50 engorging ticks cause an annual weight reduction of 5 kg per cattle and also reduction of milk products. Thus prevention and treatment are absolutely necessary. The following approaches had been done:

(A) **Non –medical or chemical methods:**

- Development of cattle breeds being resistant to ticks
 - Pasture burning to kill lurking tick stages
 - Pasture plowing and rotation
 - Alternation of livestock = e.g., use of meadows by ruminants or by horses
 - Biological control by ants, small rodents etc.
 - Spraying of spores of entomophagic fungi, which are also toxic to tick larvae
- However, all these methods never succeeded in totally eliminating these vector ticks.

(B) **Medical methods**

- Vaccination by help of vaccines (Tickgard, GAVAC, GO-TICK, TICK-VAC). They are used since the early 1990s and are rather successful. However, vaccination works only against the one-host ticks. Furthermore, vaccines offer a control of tick populations but are not sufficient to protect single animals since there is no clear knock-down effect, vaccination must be repeated all 6–10 weeks, which is time consuming and costly.

(C) **Chemical prevention and control**

- Besides “classic” insecticides (which are endangered by development of resistance), the modern macrocyclic lactones seem to be most useful, since in addition to their antitick activity they lead to deworming. However, all these products have to be used continuously.

Boophilus: Systematic Position

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

According to molecular biological examinations, this genus is now included into the genus ► *Rhipicephalus*. This is in contrast to their exterior appearance and the fact that all “former” *Boophilus* species have a one-host life cycle, while the “classic” *Rhipicephalus* species use two or three hosts.

Boophthora

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of the dipteran family Simuliidae (= black flies). See ► *Diptera*; ► *Simuliidae*; ► *Filariidae*.

Booponus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of calliphorid flies in the Philippines that induce myiasis in the feet of cattle, e.g., *B. intosa*.

Borrelia

The species of this genus are gram-negative bacteria with a species-specific length of 5–15 µm

Borrelia, Fig. 1 LM of *Borrelia burgdorferi*

Borrelia, Fig. 3 SEM of *Borrelia burgdorferi* from culture

Borrelia, Fig. 2 SEM of the bacteria stage of *Borrelia burgdorferi* on the surface of a tick intestinal cell

and 0.2–0.5 μm in width (thus they are thicker as *Treponema* spp.). They show only a few windings (Figs. 1, 2, and 3) and possess – unique in bacteria – a linear chromosome. The genes for

membrane proteins are situated on their circular and linear plasmids.

They may become cultured in artificial media and need a time of about 18 h for duplication. Some species are apathogens, others are agents of important human diseases and are transmitted by bloodsucking arthropods.

Examples are agents of:

- Endemic and epidemic relapsing fevers transmitted by ► [lice](#): *Borrelia berbera* (North Africa), *Borrelia carteri* (India), *Borrelia hispanica* (Spain), *Borrelia recurrentis* (syn. *Borrelia obermeieri*) (Africa, South America, East Asia), *Borrelia turricatae* (Central America), *Borrelia venezuelensis* (South America).
- Relapsing fever transmitted by ► [Ornithodoros](#) ticks: *Borrelia caucasica* (Near East), *Borrelia duttoni* (Central and South Africa, Madagascar), *Borrelia parkeri* (Western USA).
- Tick- or Lyme-borreliosis transmitted by ► [Ixodes](#) and ► [Dermacentor](#) ticks. *Borrelia burgdorferi* sensu lato (Europe, USA, Japan, including, e.g., *Borrelia burgdorferi* sensu strictu, *Borrelia afzelii*, *Borrelia garinii*, *Borrelia spielmani*). In Europe all types are found, in

USA occur mainly *S. burgdorferi* s.s. and in Japan *Borrelia garinii* and *Borrelia afzelii*.

- *Borrelia vincentii* is apathogenic in the respiratory tractus (syn. *Treponema*).
- *Borrelia refringens* (syn. *Treponema*) is apathogenic in the sexual tractus.

Bacterium transmitted by ► [Ticks](#) (► [Lyme Disease](#)).

Borrelia californensis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This is a *Borrelia* species of the Lyme-disease-group found at the West Coast of the USA infecting dogs and other carnivores being transmitted by *Ixodes* ticks.

Borrelia miyamotoi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This is a *Borrelia* species, which may infect dogs and immunosuppressed humans, where it induces meningoencephalitis.

Borrelia recurrentis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Bacterium transmitted by ► [lice](#).

***Borrelia* Species**

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

The genus name honors the French scientist Amédée Borrel (1867–1936).

General Information

Borrelia species belong to the bacterial order Spirochaetales, which includes the families Spirochaetaceae (*Borrelia* spp., *Treponema* spp.) and Leptospiraceae (*Leptospira* spp.). According to 16 s-rRNA analysis, the spirochetes represent a separate group of bacteria, since they are neither gram-positive nor gram-negative. The specimens of the genus *Borrelia* (Table 1) measure 8–30 µm in length and 0.2–0.5 µm in width (thus, they are thicker as *Treponema* spp.). They show only a few windings (Figs. 1 and 2) and possess – unique in bacteria – a linear chromosome. The genes for membrane proteins are situated on their circular and linear plasmids. Motility is produced by

<i>B. valaisiana</i>	<i>Ixodes ricinus</i>	Humans, rodents	Europe, Asia

Borrelia Species,

Fig. 1 Light micrograph of Giemsa-stained *Borrelia* stages

so-called endoflagella, which are situated between the inner and outer membrane and are anchored at both ends of the cylindric protoplasm (other bacteria have exoflagella). *Borrelia* species possess a very large number (more than 150) of genes encoding for proteins. Many of them are responsible for the typically broad immune-escape

possibilities of these bacteria, which can be cultured in artificial media needing about 18 h for reduplication. Many species of these *Borrelia* bacteria are apathogenic or induce only mild symptoms. However, several species are of high importance, since they may induce severe symptoms of disease. Among the genus *Borrelia* two

Borrelia Species, Fig. 2 Scanning electron micrograph of a *Borrelia* specimens on the surface of an intestinal cell of *Ixodes ricinus* (left) and scanning electron micrograph of cultured *Borrelia* stages (right)

groups of species induce especially severe diseases: ► [relapsing fever](#) and ► [Lyme disease](#) (see Table 1). The agents of both groups are ticks, whereby relapsing fever is transmitted by soft ticks and borreliosis is transmitted by hard ticks.

Borrelia: Genome

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The species of the genus *Borrelia* possess the most complex genome among the bacteria. In addition they have 12 linear and 9 circular plasmids, which enclose 610,694 base pairs. The linear chromosome contains 910,725 base pairs and shows 853 open reading frames, which encode the proteins for replication, transcription, and translation of the DNA. The replication of *Borrelia* bacteria takes long, needing 7–20 h for a reduplication by a section process.

Borrelia: Known Genospecies

Borreliosis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

The general name of this disease was chosen
honoring the French microbiologist **André
Borrel**. At first, however, the name **Lyme disease**
had been used remembering that the symptoms of

the disease have been discovered in the small village Lyme in Connecticut, USA. In former times, some symptoms of the disease had been known as **erythema migrans** = wandering skin reddening, which 1893 was described by the Danish dermatologist **A. Afzelius**. He and the French **C. Garin** as well as **W. Burgdorfer** and **A. Spielman** were honored by dedicating species names as recognition of their tremendous scientific input in the knowledge of the life cycle of

Borrelia species and of the different symptoms of disease.

Geographic Distribution/Epidemiology

The USA, Europe, and Asia, in some *Ixodes* tick regions, prevalence rates of more than 20–50 % had been diagnosed.

Agents of Disease

The disease is introduced by *Borrelia* bacteria, which are so closely related to the agents of syphilis (*Treponema pallidum*, syn. *Spirochaeta pallida*) that serological tests may show cross reactions.

Symptoms of Disease

The disease shows highly variable symptoms depending on the amount of injected bacteria and the immune status of the human host. In any way, three main phases of the disease may be diagnosed (Table 1).

Figure 1, 2 shows typical skin symptoms of borreliosis occurring at an early stage of the infection, while Figure 3 gives a survey on the different pathways and potential outcome of the clinical phases.

Borreliosis, Table 1 Main symptoms in the disease phases 1–3

Phase	Organs	Symptoms
1	Head	Headache, fever
	Skin	Migrating rosacea
	Muscles	Muscle pain
	Lymph nodes	Swellings
2	Head, spinal cord	Meningitis, meningoencephalitis
	Face	Paresis
	Heart	Inflammations
	Muscles	Pain, weakness
	Joints	Arthritis, pain
3	Skin	Acrodermatitis
	Nerves	Loss of functions
	Head	Psychosomatic problems, encephalitis
	Joints	Arthritis
	Legs, arms	Paresis

Borreliosis, Fig. 1 Early migrating rosacea

Borreliosis, Fig. 2 (a) Migrating rosacea (late phase); (b/d) lymphocytomes; (c) migrating rosacea, initial stage

Diagnosis

Serodiagnostic tests (IgM, IgG antibodies) deliver reliable results only about 4–5 weeks after infection. Direct diagnosis can be done by PCR in the late phase investigating liquor, while ELISA tests and Western blots are means for basic diagnosis. In cases, when all methods give no convincing results, the so-called lymphocyte transformation test (LTT) may offer more information. In other cases of a chronic borreliosis, a test based on the amount of CD57 cells (natural killer cells) may help, too. If there are less than 20 cells, a severe disease is postulated. Twenty to 60 cells indicate the normal status of chronically diseased patients, and more than 60 cells point on a low-graded disease, while more than 120 are mostly reached after a successful treatment. About 200 of these

CD57 cells are the normal standard of a healthy human.

Infection

The agents of disease are transmitted by blood sucking → *Ixodes* ticks, which are attached to their host for at least 8–14 h. Mechanical transmission by tabanids seems possible (e.g. *I. ricinus*, *I. scapularis*).

Prophylaxis

Avoid attachment of ticks by the use of repellents (in humans) and/or insecticides (e.g., in dogs).

Borreliosis, Fig. 3 Diagrammatic representation of the stages of the borreliosis

Incubation Period

Six to 10 days until the erythema migrans occurs (Fig. 1). However, in about 50 % of the cases, this symptom is not apparent. Paresis is first recognized about 4–6 weeks after tick bites.

Prepatent Period

About 8–14 days.

Patency

Years, if the disease is not self-healing.

Therapy

First Phase

Doxycycline (200 mg/day) for at least 14–21 days. Children below 10 years: amoxicillin.

Second and Third Phases

Cephalosporins of the third-generation (e.g., 1×2 g for 14–21 days) doxycycline for 28 days, evtl. repeated.

Borreliosis Defense System

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Tick-transmitted *Borrelia* stages are attacked inside the human skin by so-called dermal dendritic cells (DCs), which are the first to come into contact with the invaders. These cells belong to the innate immune system. Immature = unstimulated DCs recognize and engulf these *Borrelia* stages and migrate to the next draining lymph node, where antigen of the processed pathogen is presented to CD44 –T-cells, which then may introduce an adaptive immune response. In cases, when the number of available DCs falls short facing large numbers of injected *Borrelia* stages, infections become patent. Recently it has been shown that apparently tick saliva is able to sabotage DCs' responses and thus blocks immune reactions and *Borrelia* stages may reproduce.

Borreliosis: Seasonal Prevalence of Lyme Disease Spirochetes

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The different agents of ► [Borreliosis](#) are worldwide distributed being transmitted by ixodid ticks (e.g., *Ixodes ricinus*). While most vertebrate hosts harbor for shorter or longer periods, the typically shaped bacteria (time-depending on the activity of their immune system), cattle, and the heterothermic edible dormouse (*Glis glis*) show a clear seasonable prevalence of these spirochetes. These hosts become infected by tick bites during their activity phases but suppress them soon in their body. Thus in a given biotope they help to clear/diminish the infectious pressure due to *Borrelia* stages. Matuschka's and Richter's group at different Berlin Research Institutes distinguished, however, two different methods, on how these holothermic respectively heterothermic hosts overcome their invaders.

Sucker of ► [tapeworms](#), ► [Taenia](#) species.

Bothridium

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The genus of the tapeworm order Pseudophyllidea

Bothriocephalus

Genus of the cestode family Bothriocephalidae, often found in freshwater fish in the USA (e.g., the gravid proglottids of *Bothriocephalus scorpii* possess two ovaries and two uteri which are situated at their anterior and posterior poles).

Bothriocephalus acheilognathi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *bothrion* = invagination, groove; *kephalon* = head; *a* = lacking; *cheilos* = lip; *gnathos* = jaw.

General Information

This tapeworm (► *Bothriocephalus*) originates from East Asia, from where it was imported with the grassfish *Ctenopharyngodon idella* to Europe, New Zealand, and USA. According to some authors, it is a synonym of *B. gowkongensis*, which is now found in Cyprinid fish cultures with high pathogenicity. The adult worm reaches a length of 8–31 cm and a terminal width of about 2–4 mm. The scolex is heart-like and has 2 bothria as suckers. The operculated eggs are thin shelled ($50 \times 30 \mu\text{m}$) and contain already the coracidium larva, when leaving the proglottids. After infection it takes 12–20 days until the tapeworm is mature inside the fish intestine. A related species is *B. claviceps* in the eel (reaching a length of 55 cm and a width of 3 mm).

Bothriocephalus Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The species ► *B. acheilognathi*, *B. claviceps*, *B. gowkongensis*, *B. opsariichthydis*, and *B. phoxini* are important tapeworms of fish (carps) and their fish-eating final hosts.

Bottle Assay

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes a test to evaluate the status of resistance of field strains of mosquitoes. Bottles are coated inside by a given insecticide.

Mosquitoes caught in the field are immediately placed into the bottle and their survival is monitored.

Further Reading

Bouba

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Local name for mucocutaneous and cutaneous forms of leishmaniasis in South America due to *Leishmania braziliense* and *L. peruviana*. Vectors are *Psychodopygus wellcomei* (syn. *Lutzomyia*). Other names are espundia, buba.

Boutonneuse Fever

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Boutonneuse fever is caused by *Rickettsia conori*, which is widespread in Africa, the Mediterranean region, and parts of Southeast Asia. The tick bite lesion takes on a black, button-like appearance (hence the name), with a central dark necrotic area. A large number of tick species appear able to transmit the disease, which can also be acquired by contact with tick tissues when the tick is crushed, for instance when *Rhipicephalus sanguineus* is removed from dogs.

Therapy

Application of antibiotics.

Bruce, David, Sir (1855–1931)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The English military physician Major General Sir David Bruce (1855–1931) (Fig. 1) in 1895 showed that a disease of cattle – called ► [Nagana](#) by the native population – was caused by *Trypanosoma* specimens transmitted by the so-called tsetse fly. This latter name is also of African origin and refers to the flight sound of the *Glossina* flies. Before this discovery Bruce had already described the agent of the so-called **brucellosis** which he isolated in Malta from the spleen of a soldier that had died from this

Bruce, David, Sir (1855–1931), Fig. 1 Sir David Bruce

“Malta-fever.” This bacterium was later called *Brucella melitensis* being transmitted via milk from ruminants (especially goat, sheep, and cattle). Brucellosis is found worldwide as was first shown by the Danish veterinarian Bernhard Lauritz Frederik Bang (1848–1893) and is intensely correlated with the death of cow’s fetus. It was the American physician Alice Cathrine Evans (1881–1975) who showed the close relation between Bang’s and Bruce’s agents and described Bang’s agent as *Bacterium abortus* (now *Brucella abortis bovis*) in 1918. The agents of brucellosis are gram-negative, non-motile, small ($0.6\text{--}1.5 \times 0.5\text{--}0.7\text{ }\mu\text{m}$), stick-like bacteria, which do not form spores. The symptom of disease is high fever for up to 3–4 weeks due to infections of many organs. There are often cases with severe or light symptomologies.

Brugia

See Table 1. Filariidae.

Brugia, Table 1 Comparison: characteristics of *Brugia malayi* and *Brugia timori*

	<i>Brugia malayi</i>	<i>Brugia timori</i>
Microfilariae	220 μm	310 μm
Mean length	Length to width ratio = 2:1	Length to width ratio = 3:1
Cephalic space	Stained pink with Giemsa	Stained pale pink with Giemsa
Sheath	4–5 in a single row	5–8 in a single row
Terminal nuclei	31 μm	60 μm
Mean length of anlagen of organs		
Adult worms	Body length to ovijector length ratio = 360:1	Body length to ovijector length ratio = 170:1
Females	3–4 on a side, regularly spaced	3–5 on a side, irregularly spaced
Male adanal papillae		
Ecology	Various ecotypes (anthropophilic or zoophilic); transmitted by <i>Anopheles</i> or <i>Mansonia</i> spp.	One ecotype (anthropophilic); transmitted by <i>Anopheles</i>
Geographic distribution	India, Southeast Asia	Lesser Sunda archipelago, East Timor

Brugia malayi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

The genus name of this microfilarial nematode was given honoring the Italian scientist Brugi, while the species name is derived from the endemic region Malaysia.

Geographic Distributions/Epidemiology

The worm has its main spreading in humid-warm regions of Sri Lanka, India, eastern Pakistan, North and South Asia (e.g., Malaysia). About 50 million humans are estimated to be permanently infected especially in rural regions.

Morphology/Life Cycle

This species appears rather similar to ► *Wuchereria bancrofti*, since it also shares a life cycle (Fig. 1 ► *Filariidae*) between a mosquito vector and a human. The mosquito transmits the larva 3 to humans, where it grows up to the adult worm (♂♀ = macrofilarial stages), which live in the lymphatic system (lymph nodes) of humans and regional primates. The female worms give birth to motile ► *microfilariae* (viviparous propagation), the ► *sheath* of which represents the stretched former egg shell (Fig. 1d). However, besides common characteristics, *B. malayi* and *W. bancrofti* differ in several other important features. There are also significant differences to *B. malayi* (Table 1).

- (a) Adult worms of *B. malayi* are smaller than those of *W. bancrofti* (♂ 3 cm × 0.1 mm; ♀ 6 cm × 0.2 mm).

Brugia malayi, Fig. 1 Diagrammatic representation of a microfilaria of the *Brugia* type.

Brugia malayi, Table 1 *Brugia*: Comparison characteristics of *Brugia malayi* and *Brugia timori*

	<i>Brugia malayi</i>	<i>Brugia timori</i>
Microfilariae		
Mean length	220 μ m	310–325 μ m
Cephalic space	Length to width ratio = 2:1	Length to width ratio = 3:1
Sheath	Stained pink with Giemsa	Stained pale pink with Giemsa
Terminal nuclei	4–5 in a single row	5–8 in a single row
Mean length of anlagen of organs	31 μ m	60 μ m
Adult worms		
Females	Body length to ovijector length ratio = 360:1	Body length to ovijector length ratio = 170:1
Male adanal papillae	3–4 on a side, regularly spaced	3–5 on a side, irregularly spaced
Geographic distribution	India, Southeast Asia	Lesser Sunda archipelago, East Timor

- (b) Microfilariae of *B. malayi* are already formed 3 months after the infection of the host.
- (c) The microfilariae of *B. malayi* are smaller (180–250 $\times$ 6 μ m) than those of *W. bancrofti*

- and possess a different arrangement of the nuclei at the terminal end.
- (d) Most of the strains of *B. malayi* belong to the nocturna-type, i.e., the transmission occurs mainly in early and late night hours. However, some strains may appear subperiodically in the peripheral blood.
 - (e) As vectors of the microfilariae serve exclusively female mosquitoes of the genera ► *Mansonia* and ► *Anopheles*.
 - (f) The typical lymphatic swellings due to the infection with *Brugia* worms occur mainly along the legs and practically not in the urogenital system.
 - (g) Besides humans and primates, *B. malayi* is apparently able to parasitize in cats.

Symptoms of Disease

Early symptoms are lymphangitis and lymphadenitis which occur mainly along the legs, rarely in the mammae, but practically never in the abdominal or genital lymph system.

Diagnosis

Microscopical diagnosis of the microfilariae in blood smears. Methods see ► *Wuchereria bancrofti*.

Infection

Bites of bloodsucking females of the genera ► *Mansonia* and ► *Anopheles*. These species have two main sucking periods (e.g., around 10 p.m. and 4 a.m.). The development of the larvae 3 takes about 6–7 days inside the vector mosquito.

Prophylaxis

Avoiding bites of mosquitoes during sleep by use of insecticide impregnated bed nets and day-over protection by help of repellents (e.g., Viticks[®],

Doctan[®], Autan[®]). Attention: Protection time lasts only a few hours and is diminished due to sweating.

Incubation Period

30–60 days.

Prepatent Period

50–90 days.

Patency

8–10 years.

Therapy

Treatment has to be done like in infections with ► *Wuchereria bancrofti*. Mostly, a rather short treatment period (1–2 weeks) is sufficient, if a total dose of 36 mg diethylcarbamazine per kg bodyweight is given. When using doxycycline, which kills the symbionts (*Wolbachia* species) inside the worms, 100 mg/day should be ingested for 6 weeks.

Brugia timori

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This filarial nematode species occurs on the islands of the lesser Sunda Archipelago and on Timor Island. It is not completely proven whether it is an own species or just a strain of ► *Brugia*

malayi, although significant differences had been noted; see Table 1 of ► *Brugia malayi*. Transmission occurs by bites of *Anopheles barbirostris* mosquitoes.

Brugiasis, Man

Disease due to infection with the filarial worm
► *Brugia malayi*.

Main Clinical Symptoms

See ► *Elephantiasis Tropical*, ► *Filariasis Lymphatic Tropical*.

Incubation Period

30–60 days.

Prepatent Period

50–90 days.

Patent Period

8–10 years.

Diagnosis

See ► *Filariasis, Lymphatic, Tropical*.

Prophylaxis

Avoidance of mosquito bites.

Therapy

Treatment see ► *Nematocidal Drugs, Man*.

Genus of marine fish trematodes (e.g., *B. cuculus*), the species of which form branched sporocysts (e.g., in the American oyster *Crassostrea virginica*).

Bucephalus minimus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The trematode *B. (syn. Labratrema) minimus* uses as first intermediate host the edible cockle

Cerastoderma edule and is also found in *C. glaucum*, which occurs in the North-Eastern coasts of the Atlantic ocean, from the Barent Sea to Mauritania. Miracidia enter this host and reproduce there via sporocysts and rediae giving finally rise to cercariae, which penetrate into the second intermediate host, where they are transformed into metacercariae. The latter are ingested by the final host, where the adult trematode is formed. In the case of *B. minimus* the metacercariae are found in cysts in various parts of the nervous system and muscles of smaller teleost fishes like gobblids, while adults parasitize in the alimentary tract of fish predators (e.g., sea bass *Dicentrarchus labrax*).

Bugs

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Bugs belong to the insect order Hemiptera (Rhynchota). Both names derive from descriptions of morphological criteria (Figs. 1, 2, 3, and 4): The name Hemiptera comes from Greek: *hemisys* = half and *pteron* = wing, while Rhynchota points to Greek: *rhynchos* = mouth/snout and describes that these animals possess a long sucking eversible proboscis, which during use is erected but kept adjacent to the anterior body if not in use (Fig. 2). The parasitic species

Bugs, Fig. 1 Bugs. Life cycle stages of the wingless Cimicidae. (a) ► *Cimex lectularius*, bedbug and of the Reduviidae. (b) *Rhodnius prolixus*. 1 The eggs are laid in batches by *Cimex*, but mostly singly by *Rhodnius* in the crevices of bed frames, walls, or similar household sites. 2 The larvae (nymphs I) which hatch from the eggs are

wingless and feed (as do all other stages) by sucking blood of humans and of many other mammals. 3–7 Five molts of the nymphal instars are needed to reach the sexually mature female of male stage (7). In Reduviidae typical fore- and hindwings are eventually formed, but Cimicidae remain wingless in all stages

Bugs, Fig. 2 Scanning electron micrograph of the ventral side of a reduviid bug showing the attached, but protrusible sucking tube

(bed bugs and raptor bugs) belong both to the suborder Heteroptera, which possess in general four wings, whereby the anterior ones are hemi elytra, (Greek: *elytron* = cover/wing = anterior portion is thin and transparent, while the posterior portion is stiff; see *Triatoma*). Parasitic raptor

bugs such as members of the family Triatomidae (e.g., *Triatoma*, *Rhodnius*, etc., Fig. 1) have preserved their wings, but wings of bed bugs have been reduced during evolution (Figs. 1, 2, 3, and 4; Table 1). Both groups of bugs are dorsoventrally flattened and all possess so-called sexual

Bugs, Fig. 3 Light micrograph of a female bedbug (*Cimex lectularius*) with two eggs

B

Bugs, Fig. 4 Light micrograph of the so-called European predator bug *Reduvius personatus*, which may sting humans painfully (in case of defense)

Bugs, Table 1 Some common parasitic bugs

Family/species	Length (mm)	Hosts	Transmitted pathogen
Reduviidae			
<i>Rhodnius prolixus</i>	30	Humans , many animals	<i>Trypanosoma cruzi</i>
<i>Triatoma infestans</i>	30	Humans , many animals	<i>Trypanosoma cruzi</i>
<i>Panstrongylus megistus</i>	30	Humans , many animals	<i>Trypanosoma cruzi</i>
<i>Reduvius personatus</i>	18–25	Insects, humans	-
Cimicidae			
<i>Cimex lectularius</i>	5–6	Humans , mammals, birds	Eventual mechanical transmission
<i>C. hemipterus</i>	6–7	Humans , mammals, birds	Eventual mechanical transmission
<i>Oeciacus hirundinis</i>	2–3	Swallows, humans	Eventual mechanical transmission
<i>Leptocimex boueti</i>	3–4	Bats, humans	Eventual mechanical transmission

aggregation glands, which open behind the 3rd and 6th abdominal segments (tergites) in juveniles or alongside the metathorax (in adults). The (bad smelling) excretions help to unite larger groups at common places and to start mating but apparently help to repel aggressive insectivorous animals. See ► *Cimex* species; hemimetabolic development.

Bulbus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Enlargement, swelling of a worm body or its esophagus.

Bulinus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of snails, intermediate hosts of schistosomes of cattle.

Bulla

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Anchoring device of lernaepodoid crustaceans (like ► *Salmincola*) representing solidified secretions from the head and maxillary glands. The

maxillae of these parasites are often fused to the bulla.

Bullis Fever

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Disease due to transmission of agents by the tick *Amblyomma americanum*.

Bunodera

Genus of fish trematodes. ► *Digenea*.

Bunodera inconstans

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *bounos* = little hill; *deros* = skin protrusion; Latin: *inconstans* = not stabile. This genus description refers to the fact that these parasites may protrude their anterior end. These trematodes, which parasitize in the intestine of perch, pike, and trout, reach a length of only 4–5 mm, although their operculated eggs are comparably large (100 × 50 µm). Intermediate hosts are mussels and small crustaceans (*Cyclops*). Diseases occur due to inflammations and necrosis along the intestinal wall. Treatment can be done in aquaria by the water soluble praziquantel product ► *Tremazol*[®] (Fa. Alpha-Biocrine, Düsseldorf).

Bunodera Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The species of this genus of digenetic trematodes are found in the intestine of a broad spectrum of freshwater fish (perch, pike, tronts, etc.), and reach a length of up to 4.5 mm. Their anterior body is protrudable and thus forms a head-like structure. The eggs reach a size of $100 \times 50 \mu\text{m}$. Intermediate hosts are mussels and/or copepod crustaceans respectively specimens of the genus *Cyclops*.

Bunostomum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of the hookworm group, e.g., *B. phlebotomum* ($\sigma = 12\text{--}18 \text{ mm}$; $\varphi = 25\text{--}28 \text{ mm}$) in cattle, *B. trigonocephalum* ($\sigma = 12\text{--}18 \text{ mm}$; $\varphi = 22\text{--}25 \text{ mm}$) in sheep and goats.

Bunostomum Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *bunos* = little mountain, protrusion; *stoma* = mouth; *phlebos* = blood vessel; *kephale* = head; Latin: *trigonus* = triangle.

Geographic Distribution/Epidemiology

Worldwide.

Morphology/Life Cycle

- (a) *Bunostomum phlebotomum*: This species is found in the intestine of cattle, rarely in goats and stags ($\varphi = 13\text{--}29 \text{ mm}$; $\sigma = 10\text{--}19 \text{ mm}$).
- (b) *Bunostomum trigonocephalum*: This species is found in the intestine of sheep, goats, deers, etc., rarely in cattle ($\varphi = 12\text{--}29 \text{ mm}$; $\sigma = 11\text{--}20 \text{ mm}$).

For life cycle, see ► [Ancylostoma Species](#).

Symptoms of Disease

Anemia, loss of weight, diarrheas, colics, blackish feces due to blood, skin edemas, and pneumonia due to larval passage during the first 8 days p.i.

Diagnosis

Microscopical demonstration of the unembryonated eggs in the feces after the use of concentration methods (► [S.A.F.C.](#); ► [flotation](#)). *B. phlebotomum*: $75\text{--}115 \mu\text{m} \times 40\text{--}70 \mu\text{m}$; *B. trigonocephalum*: $66\text{--}104 \mu\text{m} \times 33\text{--}74 \mu\text{m}$.

Infection

Percutaneous penetration of free-living larvae 3.

Prophylaxis

Quick removal of feces from stables.

Incubation Period

One week – 10 days after penetration of larvae 3.

Wang CR et al (2013b) Sequence variability in four mitochondrial genes among *Bunostomum trigonocephalum* isolates from four provinces in China. J Helminthol 87:416–421

Prepatent Period

B. phlebotomum: 52–59 days;
B. trigonocephalum: 48–50 days.

Patency

At least 1 year.

Therapy

See ► [Ancylostoma Species](#).

²Bundeswehr Institute of Microbiology, Munich, Germany

Classification

Family of RNA Viruses, mainly transmitted by arthropods (“► [Arboviruses](#)”).

General Information

Negative-sense single-stranded tripartite RNA viruses (spherical, with envelope); about 200 species.

Bunyaviridae, Table 1 Arboviruses III. Negative sense, single-stranded tripartite RNA viruses: Family Bunyaviridae, Genus *Orthobunyavirus*

Compound that belongs to the hydroxynaphthoquinone group.
► Babesiacidal drugs; ► Theileriacidal drugs;
it blocks the electron transport in theilerian “mitochondria.”

Childhood disease due to infections with the Epstein-Barr virus causing tumors only in regions where malaria is endemic, while the virus occurs worldwide. Thus the outbreak of such lymphoma tumors is probably related with a malaria-induced immunosuppression.

Bursa Copulatrix

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Burkea eisenia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Microsporidian parasite of muscles of earthworms.

The bursa is a lobular modification of the male posterior end in some groups of ► nematodes which is highly elaborated in strongylid nematodes (Fig. 1, p. 192). During copulation, the bursa surrounds the vulvar region of the female worm (► Nematodes/Reproductive Organs).

Bursa Copulatrix, Fig. 1 DR of the terminal ends of male worms of different nematode species of horses, which are characterized by their means for

copulation. *AP* anal papillae, *BC* bursa copulatrix, *CR* cuticular rings, *SP* sense papillae, *ST* stabilizations of the BC (rays)

Bütschli, Johann Adam Otto (1848–1920)

Swiss zoologist, discoverer of many pathogenic protozoans.

Buxtonella sulcata

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Bütschliidae

Family of ciliates that live inside the intestine of mammals.

In the rumen of ruminants a large number of symbionts and commensals occur. Some of them form cysts, which can be found in the feces and may be kept erroneously for parasites (e.g.,

Buxtonella sulcata,

Fig. 1 Trophozoite and cyst of *Buxtonella sulcata* from the rumen of cattle

B

Balantidium). A very common species is *Buxtonella sulcata* (Fig. 1), which reach a size of 140 µm in diameter. It is, however, not clear whether they induce symptoms of disease. **Therapy:** Dimetridazole (e.g., Entryl® – 4 days daily 250 mg/kg bodyweight).

Further Reading

Pomajbikova K et al (2013) Novel insights into the genetic diversity of *Balantidium* and *Balantidium*-like cyst-forming ciliates. PLoS Negl Trop Dis 7, e2140

C

Caballeria liewi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Monogenean worm that parasitizes in the gills of fish of the genus *Pomadysus* and are characterized by the possession of anterior and posterior secretory adhesion systems, which are seen as three pairs of anterior-lateral pit-like openings.

Further Reading

Wong WL et al (2014) Ultrastructure of head organs and posterior secretory systems of *Caballeria liewi*. Parasitol Res 113:3935–3946

Caballonema

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of small strongylids of horses.

Cachectin

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Tumor necrose factor. See ► [Cytokines](#).

Caenorhabditis elegans

Free-living small-sized (1.3 mm in length) nematode, which is now one of the most often cultured specimens for laboratory experiments. The Nobel prize winners of the year 2006 worked with the RNA of this fully sequenced worm with a constant number of 959 cells (► [Eutely](#)) and about 19,000 genes. Most of the animals are hermaphrodites, which fertilize themselves. They are females, which as adults may produce sperms for a limited period. Males are rare, but they may copulate with the hermaphroditic females.

Calabar Swelling

► [Oedema](#) due to infection with wandering ► [Loa loa](#) stages in human skin, ► [Filariidae](#), ► [Loiasis](#).

Calcareous Corpuscles

The ► [tegument](#) and parenchymal cells of adult and in particular larval ► [tapeworms](#) contain these significant corpuscles (Fig. 1), which may be used for diagnosis (► [Cestodes](#)/► [Tegument](#)). They are composed of an organic base coupled with inorganic substances, such as potassium, sodium, magnesium, calcium, phosphate, and sulfate in different ► [Cysticercus](#) larvae. In adult tapeworms CaO, MgO, P₂O₅, and CO₂ were determined. The organic base of the corpuscles includes DNA, RNA, proteins, and glycogen. The function of these organelles, which (after KOH isolation) in electron microscopy appear as concentrically lamellated platelets, is not quite clear. Since they are mainly produced in the absence of oxygen, they were thought to buffer anaerobically produced acids. It has also been suggested that they are a reservoir for inorganic ions. It was recently reported that calcareous corpuscles are also formed in the excretory canals of cysticerci of ► [Taenia solium](#) indicating their

possible contribution in osmoregulation and protection against calcification.

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Calcium binding protein in the flagellar membrane of ► [Trypanosoma brucei](#) and *T. cruzi*.

Calicophoron

Genus of flukes related to ► [Paramphistomum](#), e.g., *Calicophoron* (syn. *Paramphistomum*) *daubneyi* in deers.

Calicophoron daubneyi

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This fluke species parasitizes in the rumen of livestock ruminants and of deer.

Further Reading

Calcareous Corpuscles, Fig. 1 Calcareous corpuscles inside a protoscolex within an *Echinococcus* brood capsule.

Calicophoron Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The species of this genus (*C. daubneyi*, *C. microbothrium*) are synonyms of the genus ► *Paramphistomum*. They live as other species of the genus *Paramphistomum* in the rumen of ruminants. Intermediate host of *C. daubneyi* are *Galba truncatula* snails in France, where in several regions prevalence rates of 10–20 % were reached.

Further Reading

Calliphora

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *kalos* = beautiful, *phorein* = porting, showing.

Genus of ► *Diptera*, belonging to the fly family Calliphoridae appearing with black thorax and steely dark-blue, bluish-violet, or blue-black, slightly metallic abdomen. This group of flies is also called “bluebottles” reaching a length of 10–14 mm as adults. In Europe occur *C. vicina*

Calliphora, Fig. 1 LM of an adult *Calliphora erythrocephala* fly and its pupa

Calliphora, Fig. 2 LM of *Calliphora* eggs close to the border of a 10-cent coin

(syn. *erythrocephala*) (Fig. 1), and *C. vomitoria*, also named “blue flesh flies.” The eggs are ovoid and appear white (Fig. 2).

Callitroga

Genus of flies, the larvae of which penetrate human skin leading to myiasis. The species *C. americana* is synonym to *Cochliomyia hominivorax*. The common name for this group of flies is “screwworms” or “-flies.” ► [Diptera](#).

Calodium hepaticum

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonym for *Capillaria hepatica*. See ► [Capillaria](#) species of animals and ► [Capillaria](#) species of humans.

Further Reading

Führer HP (2013) An overview on the host spectrum and distribution of *Calodium hepaticum*. Part 1, 2. Parasitol Res. doi:10.1007/s00436-013-3692-9

Caloglyphus berlesi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Mite which lives in food. However, skin contact with sheep and humans may introduce severe skin irritations.

Calpain

This product is released by the skin – penetrating cercariae of schistosomes. It is postulated to lead

to a Th1 cytokine production, which may introduce protection of the host.

Calreticulin

This is a calcium-binding protein (e.g., of trypanosomes), which is suggested to modulate the vertebrate complement system and provides an effective immune-escape mechanism for, e.g., *T. cruzi*. Since it also inhibits angiogenesis it might protect the host from ongoing neoplastic aggressions.

Calypstrate Flies

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Families with medical importance are:

Calliphoridae, Fanniidae, Glossinidae, Hippoboscidae, Muscidae, Oestridae, Tachinidae.

Calyptospora

► [Coccidia](#); Genus of parasites of fish, e.g., *C. funduli* is found in Cyprinodontidae and Atherinidae and needs intermediate hosts (shrimps) to complete the life cycle.

Camallanus

Genus of ► [nematodes](#). Several of these red appearing species (e.g., *C. cotti*) live in the hind gut of fish and parasitize by blood sucking (Fig. 1). Since they possess a fortified buccal capsule (Fig. 2), they are also called “fraise-head-worm.” Males reach 3–4 mm in length,

Camallanus, Fig. 1 The posterior end of a female *Camallanus* hangs out of the anus of its host (*Papiliochromis* sp.)

Camallanus, Fig. 2 LM of the buccal capsules of a *Camallanus* – nematode

females grow up to 7–12 mm, hang out of the anus, and excrete larva – containing eggs into the water (Fig. 1). These eggs are taken up by intermediate hosts (small crustaceans), within which the infectious larva 3 develops. The infection of the fish (final host) occurs by feeding such intermediate hosts.

Symptoms of Disease

Apathy, anaemia, slow growing, disturbance of bone formation, death due to bacterial superinfections.

Therapy

Medical bath containing compounds such as emamectine (Nematol®) or mosquito-larvae that had been traced with levamisole or fenbendazole (~50 mg/kg food).

Camelid Infectious Disorders

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Camels are very important carriers in many regions of the world and thus they may come in contact to a broad spectrum of agents of diseases on their ways in rural regions or when kept as food animals. The book of the three authors Wernery, Kinne, and Schuster shows all important agents of camel disease including parasite and recent means of treatment.

Campanulotes bidentatus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Featherling (mallophage) of house doves (*Columbicola columbae*).

Campylobacter coli

Bacterium, the presence of which facilitates in pigs the mucosae invasion of the ciliate ► *Balantidium coli*.

Canalis gynaecophorous

In schistosomes the dorso-ventrally flattened male forms a groove, within which the tiny female – appearing circular in diameter – is hidden. This partnership keeps for the whole lifespan.

Candida

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of fungi species (e.g., *C. albicans*) found on human skin as well as in intravaginal infections or in lung infections, e.g., of AIDS patients.

Candiru

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Brazilian name of a cat fish species ► *Vandellia cirrhosa* that lives in the rivers Amazonas and Orinoco. The fish reaches a maximum length of 17 cm. As young tiny stages, they are known to penetrate occasionally into the anus and/or into genital openings of humans, wherein they suck blood and thus were called vampire fish. Since they grow rapidly and since they possess teeth at the mouthparts and backward directed spines at

each cover of their gills, they are mostly unable to leave these human cavities and have to be removed surgically. These fish (also called “caneros”) had been described by early expeditioners such as Cuvier and Valenciennes (1846) and De Castelnau (1855) and gave occasion to many “horror stories.” Descriptions, however, show that these events of human penetration are extremely rare cases and of course do not occur, when humans wear bathing suits.

Capacitation

The last stage of spermiogenesis in ► ticks, leading to mature sperms (► Ticks/Spermatogenesis and Fertilization).

Capillaria putori

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonym for *C. mustelorum* (see ► Capillaria species of animals), which is found in the stomach of cats in Germany.

Capillaria Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *capillus* = hair of the head, *annulatus* = ringlike, *anatis* = belongs to ducks, *contortus* = twisted, *bos* = cattle, *hepar* = liver, *aerophila* = air loving, *plica* = fold, and *philippinensis* = belongs to the Philippines.

Geographic Distribution/Epidemiology

Worldwide occurrence in different densities and epidemics in crowded farms or in rural regions, often also in rodents.

Morphology/Life Cycles

There are several species, which use different animals as final hosts (see Table 1); however, some of them (e.g., *Capillaria aerophila*, *C. hepatica* (syn. *Calodium hepaticum*), or *C. philippinensis*) parasitize also in humans (Fig. 1). The adults live in species-specific organs (e.g., *C. annulata* in crop and the esophagus; *C. philippinensis*, *C. obsignata*, and *C. bovis* in

Capillaria Species, Table 1 Important *Capillaria* species, which are all tiny, since their diameter is less than 1 mm

Species	Hosts	Habitat	Length ♀(cm)	Length ♂(cm)
<i>C. annulata</i>	Chicken	Esophagus	3	1,5
<i>C. contorta</i>	Chicken, ducks	Esophagus	1–2	1
<i>C. obsignata</i>	Many birds	Intestine	1,2	0,8
<i>C. anatis</i>	Goose, ducks	Cecum	1,8	1
<i>C. bovis</i>	Ruminants	Intestine	2,2	1,5
<i>C. aerophila</i>	Carnivores, humans	Trachea	2	1,7
<i>C. plica</i>	Carnivores	Blades	6	3
<i>C. hepatica</i>	Rodents, rabbits, humans	Liver	10	4

Capillaria Species, Fig. 1 (A–D) Life cycle of *Capillaria hepatica*. (A) Adults (male 15–30 × 0.06 mm, female 100 × 0.2 mm) live in the liver ► [parenchyma](#) of their final hosts (rodents and a variety of other mammals). Here the females (1) deposit their typical eggs (EG), which measure 45–60 × 30 µm and are characterized by two ► [polar plugs](#) (PPs). (B) The unembryonated eggs have no means of egress until eaten by a predator (mainly foxes, dogs) or until the liver decomposes after death of the final host. In the first case, the eggs merely pass through the intestine of the predator and are excreted with the feces. (C) Embryonation occurs on the soil and depends on a favorable combination of temperature, moisture, and oxygen. At

room temperature about 4–5 weeks are needed until the first-stage larva (L_1) is formed, which may survive for more than 1 year. (D) Infection of final host (A: mice and erroneously man) occurs by swallowing of fully developed eggs. After hatching in the cecum, the L_1 reaches (via the intestinal wall and portal vein) the liver within 2 days. There, the next two larval stages (2, 3) are formed by molts; maturity is acquired 21–28 days after infection (prepatent period). The life span of males is about 40 days and that of females about 60 days (patent period). The eggs, however, persist until the death of the final host. EG egg, GA genital anlagen, GO genital opening, L larva, PP ► [polar plug](#), ST stichosomal cell of the esophagus

the small intestine; *C. plica* in the urine bladder; *C. hepatica* in the liver). The larva 1 develops inside the excreted eggs within 1–2 weeks. These larvae 1 may be ingested directly by the

final hosts (Table 1) or by an earthworm (e.g., *C. annulata*, *C. aerophila*), wherein the larva 3 has been developed as in the eggs of the other species, which lay on earth.

Capillaria Species, Fig. 2 Light microscopical photo of an egg of *Capillaria* from feces

Symptoms of Disease

Depending on the species and depending on the amount of excreted eggs, respectively, ingested eggs, the symptoms may vary in intensity. Catarrhally and hemorrhagic inflammations, fibrosis, anemia, disturbances of resorption, diarrheas, and weight loss often occur. In the case of liver infections, severe disturbances in the metabolic processes are often diagnosed. Infected animals show the symptoms icterus, anorexia, and vomiting.

Diagnosis

Determination of eggs in the different media:

1. *C. hepatica* and *C. aerophila*: liver biopsy
2. Other species: eggs in intestinal fluid

The eggs (Fig. 2) are characteristic and appear similar like those of ► *Trichuris* species; however, the two polar plugs are practically not protruded. *C. hepatica* eggs are finally situated in the liver

Capillaria Species, Fig. 3 Light micrograph of a nest of *C. hepatica* in the liver of a rodent

parenchyma (Fig. 3), from where they cannot get out except the liver that is fed by a carnivorous animal.

Infection

Depending on the species: ingestion of infectious eggs from soil, uptake larvae within earthworms, or ingestion of eggs in the liver of hosts (in the case of *C. hepatica*) (Fig. 1).

Prophylaxis

In animal stables: avoiding of entrance of wild animals and regular discharge of feces. For humans: washing of vegetables (*C. hepatica*), respectively, cooking of meat and fish.

Incubation Period (Examples)

- *C. aerophila*: ~7–10 days
- *C. bovis*: 7–14 days
- *C. anatis*: ~7 days
- *C. hepatica*: ~1–2 days

Prepatent Periods (Examples)

- *C. hepatica*: 21–28 days (eggs stay in the liver)
- *C. annulata*: 18–26 days
- *C. contorta*: ~50 days
- *C. obsignata*: ~22 days
- *C. anatis*: ~28 days
- *C. bovis*: ~60 days
- *C. plica*: ~60 days
- *C. aerophila*: ~30–40 days

Patency

C. hepatica, 4–7 weeks; other species about 1 year.

Therapy

Birds: flubendazole and levamisole. Mammals (dogs, cats): albendazole, ivermectin, fenbendazole, and mebendazole.

Capillaria Species of Animals

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: *capillus* = head hair; *annulatus* = with rings; *anatis* = belonging to ducks; *contortus* =

twisted; *bos* = cattle, *ox*; *hepar* = liver; *aerophila* = air loving; *plica* = folding; English: capillary worms.

Geographic Distribution/Epidemiology

Worldwide especially in farmed animals, but also in many wild relatives. In cases of overfilled cages or stables little epidemics may occur.

Morphology/Life Cycles

The mostly very tiny, hair-like appearing specimens measure in general only a few cm (see Table 1). The life cycles may run directly (e.g., in *C. bovis*, *C. contorta*) or may involve transportation hosts such as earthworms (e.g., *Lumbricus*, *Eisenia* species). The parasitized sites inside their final hosts differ with respect to the different species and to their regular host (Table 1). In the case of *C. hepatica* adult stages live in the liver tissues of their hosts, where their eggs stick tight. If carnivores feed such hosts, the eggs are set free inside their intestine and appear within the feces. This is the chance to become ingested by another host. Thus also carnivores (and humans) may become final hosts of *C. hepatica*. However, further transmission would only occur if humans are ingested by carnivores.

Symptoms of Disease (Capillariasis)

Depending on the intensity of the infection and on the parasitized regions of the host bodies the observed symptoms may vary considerably. Thus the following symptoms have been described by various authors: catarrhic and hemorrhagic inflammations, fibrosis of the mucous layers, anemia, diarrhea, reduced resorption of food, and loss of weight. In case of the infection of the liver (Fig. 1) by *C. hepatica* massive malfunctions of the metabolism may occur: combined anorexia, vomiting, and icterus. Icterus is often seen in human infections with *C. hepatica*, while vomiting and lung problems are seen in cases of infections with *C. aerophila*.

Capillaria Species of Animals, Table 1 Important species of the genus *Capillaria*

Species	Hosts	Tissue	Length ♀ (cm)	Length ♂ (cm)
<i>C. annulata</i>	Gamefowl	Esophagus	3	1.5
<i>C. contorta</i>	Chicken, ducks	Esophagus	1–2	1
<i>C. obsignata</i>	Many bird species	Small intestine	1.2	0.8
<i>C. anatis</i>	Geese, ducks	Cecum	~1.8	1
<i>C. erinacei</i>	Hedgehogs	Stomach	Up to 1.3	0.6
<i>C. bovis</i>	Ruminants	Small intestine	~2.2	1.5
<i>C. aerophila</i>	Carnivores, humans	Lung	~2	1.7
<i>C. plica</i>	Carnivores	Bladder	Up to 6	Up to 3
<i>C. mustelorum</i>	Cats	Stomach	Up to 8.5	Up to 4
<i>C. hepatica</i>	Rodent, rabbits, humans	liver	Up to 8	Up to 4

Capillaria Species of Animals,

Fig. 1 Diagrammatic representation of the life cycle of *Capillaria plica*

Diagnosis

For diagnosis of capillariasis the typical eggs must be obtained. These eggs look similar to those of *Trichuris* species; however, both polar plugs of the eggs are not protruding, so that the poles appear more or less rounded (Fig. 2). These eggs can be obtained by microscopic investigation of eggs after use of concentration methods (► S.A.F.C.). The eggs of intestinal worms are found in the feces, those of *C. aerophila* in addition into the sputum, those of *C. plica* in the urine, while those of *C. hepatica* within intermediate hosts such as

rodents, rabbits, and also humans can only be found in liver biopsies.

Infection

The oral uptake of infectious eggs occurs in most species via contaminated food. However, the cycle of *C. hepatica* is only closed if carnivores eat eggs inside infected livers of their prey (e.g., hare, rabbits, rodents). Humans can be infected by worm eggs. However, humans may also excrete eggs after eating raw infected liver.

Capillaria Species of Animals, Fig. 2 Light micrograph of nematode eggs of dogs. Note that the egg of Capillaria has two plugs (PF), LA larva, Milbe = mite

Prophylaxis

Avoiding introduction of eggs into stables by wild animals and regular elimination of feces from stables.

Incubation Periods

<i>C. aerophila</i> :	~7–10 days
<i>C. bovis</i> :	7–14 days
<i>C. anatis</i> :	~7 days
<i>C. hepatica</i> :	~1–2 days

Prepatent Periods (Examples)

<i>C. hepatica</i> :	21–28 days (eggs stick in the liver of intermediate hosts)
<i>C. annulata</i> :	8–26 days
<i>C. contorta</i> :	~50 days
<i>C. obsignata</i> :	~22 days
<i>C. anatis</i> :	~28 days
<i>C. bovis</i> :	~60 days
<i>C. plica</i> :	~60 days
<i>C. aerophila</i> :	~30–40 days

Patency

<i>C. hepatica</i> :	~4–7 weeks (only) in carnivores
<i>C. bovis</i> :	~1 year
<i>C. aerophila</i> :	~1 year
<i>C. annulata</i> :	~1 year
<i>C. obsignata</i> :	~1 year

Therapy: Birds

Fenbendazole (1 × daily 50 mg/kg for 10 days, oral), levamisole (7.5 mg s.c. on 2 days). **Mammals (cats, dogs):** ivermectin, levamisole, mebendazole/fenbendazole.

Capillaria Species of Humans

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *capillus* = hair of head; *philippinensis* = belongs to the Philippines. English: capillary.

Geographic Distribution/Epidemiology

Worldwide occurrence in different densities; epidemics in crowded farms or in rural regions.

Morphology/Life Cycles

There are several species, which use different animals as final hosts (see ► [Capillaria species](#) of animals); however, some of them (e.g., *Capillaria aerophila*, *C. hepatica* (syn. *Calodium hepaticum*) or *C. philippinensis*) parasitize also in humans (Fig. 1). The adults live in species-specific organs (*C. philippinensis* in the small intestine; *C. hepatica* in liver). Adults of *C. hepatica* are long (♀ = 8–10 cm, ♂ = 3 cm), while those of *C. philippinensis* are tiny (♀ = 3 cm, ♂ = 3 mm). The larva 1 develops inside excreted eggs within 1–2 weeks. These larvae 1 may be ingested directly by the final hosts or by an earthworm (e.g., *C. aerophila*), wherein the larva 3 develops as it occurs in the eggs of the other species. In the case of *C. philippinensis* water birds and/or crustaceans may become involved as intermediate hosts, while there are none in *C. hepatica*. The adults of *C. hepatica* live in the parenchyma of the liver of lagomorphs and rodents; however, also humans may become infected, too, if they eat raw liver of infected animals. Since the eggs produced by these worms stick tight in the liver, these eggs can never be found in human feces. However, if such eggs are seen nevertheless, they have their origin in eggs taken up during eating infected liver of animals.

Symptoms of Disease (Capillariasis)

Depending on the species and depending on the amount of excreted eggs respectively depending on ingested eggs the symptoms may vary in intensity. Often catarrhalic and hemorrhagic inflammations, fibrosis, anemia, disturbances of resorption, diarrheas, and weight loss occur. In case of liver infections severe disturbances in the metabolic processes are often diagnosed. Infected animals and humans show the symptoms icterus, anorexia, and often vomiting.

Diagnosis

Determination of eggs in the different media:

Capillaria Species of Humans, Fig. 1 *Capillaria* species. (a–d) Life cycle of *Capillaria hepatica*. (a) Adults (male 15–30 × 0.06 mm, female 100 × 0.2 mm) live in liver ► **parenchyma** of their final hosts (rodents and a variety of other mammals). The females (*I*) deposit there their typical eggs (EG), which measure 45–60 × 30 µm and are characterized by two ► **polar plugs** (PP). (b) The unembryonated eggs have no means of egress until eaten by a predator (mainly foxes, dogs) or until the liver decomposes after death of the final host. In the first case the eggs merely pass through the intestine of the predator and are excreted with the feces. (c) Embryonation occurs on the soil and depends on a favorable combination of temperature, moisture, and oxygen. At room

temperature about 4–5 weeks are needed until the first-stage larva (*L*₁) is formed, which may survive for more than 1 year. (d) Infection of final host (a: mice and erroneously man) occurs by swallowing fully developed eggs. After hatching in the cecum the *L*₁ reaches (via the intestinal wall and portal vein) the liver within 2 days. There, the next two larval stages (2, 3) are formed by two successive molts; maturity is acquired 21–28 days after infection (prepatent period). The life span of males reaches about 40 days and that of females about 60 days (patent period). The eggs, however, persist until the death of the final host. EG egg, GA genital anlagen, GO genital opening, *L* larva, PP ► **polar plug**, ST stichosomal cell of esophagus

1. *C. hepatica*, *C. aerophila*: liver biopsy; egg size: 50 × 35 µm
2. Other species: eggs in intestinal fluid (see ► *Capillaria* species of animals)

The eggs are characteristic and appear similar like those of *Trichuris* species; however, the two polar plugs are practically not protruded. *C. hepatica* eggs are finally situated in the liver parenchyma (Fig. 1),

from where they cannot get out except the liver is ingested by a carnivorous animal.

Infection

Depending on the species the following modes may occur: ingestion of infectious eggs from soil, uptake of larvae within earthworms, or ingestion of eggs in the liver of hosts (in the case of *C. hepatica*) (Fig. 1).

Prophylaxis

In *animal stables*: avoiding of entrance of wild animals; regular discharge of feces; for *humans*: washing of vegetables (*C. hepatica*) respectively cooking of meat and fish.

Incubation Period

- *C. hepatica*: ~1–2 days

Prepatent Periods (Examples)

- *C. hepatica*: 21–28 days (eggs stay in liver)
- *C. philippinensis*: 18–26 days
- *C. aerophila*: ~30–40 days

Patency

C. hepatica: 4–9 weeks; other species about 1 year.

Therapy

Birds: flubendazole, levamisole; mammals (dogs, cats): albendazole (1–2 × 400 mg per day for 3 weeks), mebendazole (2 × 200 mg per day).

Capillariasis

Capillariasis is diagnosed by finding the distinctive ► *Trichuris*-like eggs either in the liver (► *Capillaria* species) or in the feces (*C. philippinensis*). In *C. hepatica* infection the embryonated eggs are ingested with soil, and the larvae mature in the liver where adults lay their eggs. They have been found in a number of humans, surrounded by fibrosis. Because *C. hepatica* is normally found in rats, the adults die in humans. Infection with *C. philippinensis* has been described in Thailand and the Philippines. Large numbers of ► *viviparous* adults, larvae, and eggs have been found in the lumen and mucosa of the small intestine of people who are believed to have been infected by eating raw freshwater fish. ► *Autoinfection* with larvae appears to explain the intensity of the infection. Severe protein-wasting enteropathy with edematous jejunal walls but with little inflammation and an inconstant presence of eosinophils are considered characteristic. Malabsorption with voluminous diarrhea, followed by emaciation, and hypoproteinemic edema, often precedes a fatal outcome after an illness of 2 weeks to 2 months.

Therapy

Nematocidal Drugs, Man.

Blood Disease, Animals (Parasitemias)

Hemoprotozoal diseases (► *Babesiosis, Animals*, Trypanosomosis, Animals, ► *Theileriosis* and ► *Leishmaniosis, Animals*) are caused by infections which localize either in the blood alone or in the blood and solid tissues. Blood infections affect primarily the microcirculation. However, more important are the lesions caused in solid tissues and organs. They are attributable either to systematic malfunction of the circulation or to disturbances in the microcirculation of a specific organ. An important common feature in all the pathogenesis is the release of large amounts of antigens into the

plasma. The interactions of these antigens with the host's immunological responses result also in mechanisms of tissue destruction.

The clinical signs are nonspecific and consist of fever, lethargy, weakness, and emaciation. Parasitemias are often associated with ► [anemia](#), leukopenia, ► [edema](#), and hemorrhages (Table 1).

Heart

Most parasites which form cysts in striated muscles may also invade the myocardium. Such cysts include the tiny tubular sarcocysts formed by the protozoan ► [Sarcocystis](#), the metacestodes of the ► [Taeniidae](#) (cysticerci and hydatid cysts), or the encysted larvae of the nematode ► [Trichinella spiralis](#). These infections generally produce few or no symptoms and in most cases the cysts are found incidentally on postmortem examination of the cardiac muscle. However, in the unusual event of a massive infection, death may occur after a febrile course.

The pathognomonic lesion in *Gedoelestia*-fly larva infection (► [Uitpeuloog](#)) is a thromboendophlebitis which varies in intensity, location, and distribution and is frequently accompanied by thromboendoarteritis. In sheep coronary thrombosis causes myocarditis or myomalacia cordis with sudden death as the sequel.

Trypanosoma cruzi is the cause of human trypanosomosis in South America (► [Chagas' Disease, Man](#)). It also develops and causes disease in cats, dogs, and pigs which, together with numerous wild animals, act as ► [reservoir hosts](#) for the parasite. *T. cruzi* multiply within the ► [cytoplasm](#) of the cells of their mammalian host, particularly those in the skeletal and cardiac muscles (amastigote form). The heart is particularly affected, with development of multifocal to diffuse severe granulomatous myocarditis. In dogs nonspecific clinical signs such as ► [weight loss](#), lymphadenomegaly, ► [diarrhea](#), and ► [anorexia](#) are generally accompanied by signs referable to cardiac dysfunction, such as tachycardia, ascites, weak pulse, lethargy, and hepatomegaly.

Vasculitis

The tachyzoite stage of *Toxoplasma gondii* invades many host cell types including vascular endothelium. Perivascular infiltration, e.g., in the brain is a common feature in toxoplasmosis-related inflammation. High infective doses of pathogenic *Sarcocystis* spp. (e.g., *S. cruzi*, *S. miescheriana*) may cause multiple hemorrhages in the intermediate host. The pathogenesis is not completely resolved but it appears that both mechanical destruction of the endothelial lining by the intracellularly developing parasite and alteration of blood coagulation are involved.

Hemoprotozoa (► [Cardiovascular System Diseases, Animals/Parasitemia](#), ► [Babesia](#), ► [Theileria](#), ► [Leishmania](#), ► [Trypanosoma](#)) do not only destroy host cells but also induce occlusion of capillaries and immune complex formation. This leads to necrosis and inflammation in various tissues. Severe, often lethal, disease results from organ malfunction; however, the clinical picture may be quite variable, depending on the main localization of impairment of microcirculation. Moreover, generalized disorder of circulation and acute shock are possible consequences of hemoprotozoan infection.

Arteries

Parasitic arteritis is a very common form of arterial disease in animals (Table 2). The lesions are characterized by inflammatory reaction and thickening of the arterial wall, often accompanied by endothelial damage and thrombosis. Thrombi may partially or completely occlude the artery, and emboli arising from pieces of thrombi that have broken loose may occlude vessels distal to the site where parasites have lodged. Rupture of arteries as a result of parasitic lesions is rare. The two helminth species which cause by far the most severe damage to arteries are ► [Strongylus vulgaris](#) in horses and ► [Dirofilaria immitis](#) in dogs. Other species eliciting varying degrees of arteritis are *Onchocerca armillata* in cattle, *Elaeophora schneideri* in sheep, *Angiostrongylus vasorum* and ► [Spirocerca lupi](#) in dogs, and *Aelurostrongylus abstrusus* in cats.

Cardiovascular System Diseases, Animals, Table 1 Parasites of the hematopoietic system (According to Vercruysse and De Bont)

Parasite	Host	Location	Clinical presentation	Principal lesions
<i>Babesia</i>				
<i>B. bigemina</i>	Cattle	Red blood cells	Fever, malaise, loss of appetite, listlessness, anemia hemoglobinuria, icterus	Findings of acute intravascular hemolytic crisis: capillary congestion of most organs, splenomegaly
<i>B. bovis</i>	Cattle		<i>B. bovis</i> , <i>B. canis</i> : nervous symptoms	<i>B. bovis</i> , <i>B. canis</i> : congestion gray matter throughout the brain
<i>B. divergens</i>	Cattle			
<i>B. major</i>	Cattle			
<i>B. caballi</i>	Horse			
<i>B. canis</i>	Dog			
<i>B. gibsoni</i>	Dog			
<i>B. felis</i>	Cat			
<i>Leishmania</i>				
<i>L. infantum</i>	Dog	Monocyte-macrophage system (visceral and cutaneous)	Lymphadenomegaly, anemia, splenomegaly, dry exfoliative dermatitis, ulcerations, weight loss, onychogryphosis, ocular signs, anorexia	Hemo-lymphatic hypertrophy with macrophage proliferation and focal granulomas
<i>Theileria</i>				
<i>T. parva</i>	Cattle	Lymphocytes (lymphoblasts), erythrocytes	E C F: fever, dullness, listlessness, anorexia, hyperplasia lymph nodes, salivation, lacrimation diarrhea, watery cough, and dyspnea	Lymphoid hyperplasia, splenomegaly, petechial hemorrhages over most of the serous and mucous surfaces, interlobular edema, emphysema and hyperemia of the lungs
<i>T. annulata</i>	Cattle			
<i>T. lawrencei</i>	Cattle			
<i>T. mutans</i>	Cattle			
<i>T. hirci</i>	Sheep, goats			
<i>T. equi</i>	Horse			
<i>Trypanosoma</i>				
<i>T. congolense</i>	Ruminants	Blood plasma, perivascular tissues	Acute: severe symptoms and death after 3 weeks Chronic: remittent fever, anemia and progressive emaciation. Less common: watery diarrhea, abortion, stillbirths, corneal opacity, bottle jaw	Generalized lymphadenopathy; heart is flabby; liver and spleen are enlarged
<i>T. vivax</i>	Ruminants, horses			
<i>T. evansi</i>	Horses, dogs			
<i>T. brucei</i>	Equines, ruminants, dogs, cats			
<i>T. simiae</i>	Pigs			

ECF East Coast fever

Strongylus vulgaris is often referred to as the most pathogenic nematode parasite of horses. It is widely distributed and infects horses of all ages, fatal natural infection having been observed in

foals as early as 21 days after birth. The pathogenesis of *S. vulgaris* infection is associated with the larval migration of the parasite through the tissues of the host. Third-stage infective larvae

Cardiovascular System Diseases, Animals, Table 2 Parasites inducing myocarditis and vasculitis (According to Vercruyse and De Bont)

Parasite	Host	Location	Clinical presentation	Principal lesions
Nematoda				
<i>Angiostrongylus vasorum</i>	Dog, fox	Pulmonary artery	Dyspnea	Granulomatous interstitial pneumonia, endarteritis
<i>Dirofilaria immitis</i>	Dogs, rarely other hosts	Pulmonary arteries and chambers of the right heart	Deep soft chest cough, loss of exercise tolerance, emaciation	Intense endovascular reaction of the pulmonary arteries sometimes in hepatic veins
<i>Elaeophora schneideri</i>	Sheep, deer, elk	Cephalic arteries	Hyperplasia and occlusion of cephalic and other arteries; microfilariae cause dermal lesions	Mild intimal sclerosis to prominent fibrous thickening of the vessel wall
<i>Onchocerca armillata</i>	Cattle	Thoracic aorta	Microfilariae cause epileptiform signs and ophthalmia	Nodules, roughening, and calcifications in the aortic walls
<i>Spirocerca lupi</i>	Dog	Aorta	Usually no clinical signs during the prepatent phase	Local thickening of the intima and media of the aorta
<i>Strongylus vulgaris</i>	Equines	Anterior mesenteric artery and the adjacent aorta and other trunks	Pyrexia, anorexia, weight loss, dullness, colic, and death in severe infections, otherwise varying pyrexia, colic, diarrhea	Vermineous arteritis, thrombus formation, infarction of colon and cecum
Protozoa				
<i>Trypanosoma cruzi</i>	Man, wild mammals, dog, cat, pig	Amastigote forms preference for skeletal and cardiac muscle	Systemic disease, cardiac dysfunction as tachycardia ascites, weak pulse, lethargy	Heart: mild multifocal to diffuse severe granulomatous myocarditis
Trematoda				
<i>Schistosoma curassoni</i> ,	Ruminants	Mainly mesenteric and portal veins	Mucoid and hemorrhagic diarrhea, anorexia, loss of condition, general weakness, anemia, hypoalbuminemia	Granulomatous lesions in intestine and liver
<i>S. bovis</i> , <i>S. mattheei</i>	Ruminants, horses			

ingested by the grazing animal penetrate the wall of the intestine, molt in the submucosa to become fourth-stage larvae, and invade terminal branches of intestinal arteries to begin their migration. This penetration and early migration of larvae results in inflammatory reactions and small hemorrhages throughout the intestinal wall. This coincides with the rise in body temperature detected 5–7 days after heavy infections. The temperature reaction generally subsides as the fourth-stage larvae migrate in the intima of the mesenteric arteries causing inflammatory reactions and

mural thrombi. By 2–3 weeks post-infection, the larvae reach the cranial mesenteric artery where they remain for several months. They molt to become fifth-stage larvae and eventually return to the lumen of the large intestine where they complete their maturation and start producing eggs 6–7 months after infection. During their long stay in the cranial mesenteric artery, the larvae induce a severe fibrinous inflammatory reaction which can involve all layers of the arterial wall (verminous arteritis). In ► **chronic infections**, the wall of the artery becomes thickened and the

lumen partly occluded by thrombi, cellular debris, and larvae which remain firmly attached to the intima. Clinical signs in animals include dullness, progressive weight loss, and varying degrees of pyrexia, often with intermittent abdominal discomfort. At postmortem, aneurysmal dilatation of the artery may sometimes be observed. Larval migration of *S. vulgaris* was generally recognized as a major etiological factor of equine colic, although its incidence is decreasing due to the availability of efficient anthelmintics. Acute colic due to thromboembolic infarction of the cecum or large intestine is a well-documented complication of verminous enteritis. Colic signs have also been observed in early massive infections, before verminous lesions develop in the cranial mesenteric artery. Possible mechanisms for colic include damage to and impairment of innervation to the intestine by migrating larvae, release of toxins by degenerating larvae, and hypersensitivity or allergic reactions to *S. vulgaris*. A diarrheic syndrome in field cases of verminous arteritis has also been described. The pathophysiology is poorly understood but it may be a response to altered intestinal circulation, local irritation, and/or severe ulceration of the mucosa of the cecum and colon caused by thromboembolism. Clinical signs and lesions have been associated with aberrant larval migration in the aorta; in the coronary, iliac, spermatic, and renal arteries; and in the heart, kidney, brain, and spinal cord.

The filarial worm *Dirofilaria immitis*, or “► heartworm,” is an important parasite of the dog. The adult worms are 12–30 cm long and live in the right ventricle of the heart and in the pulmonary arteries. Infection occurs after transmission of infective larvae (L3) by mosquitoes. Most cases with light infection remain asymptomatic. In heavier infestations, the presence of large numbers of heartworms does both mechanically interfere with the circulation through the right heart and lungs and induces endarteritis with severe intravascular changes. Such heavy infection invariably leads to

circulatory and respiratory distress. The mechanical interference with the circulation through the right heart generally causes a compensatory hypertrophy of the right ventricle. At the same time, adult worms and juveniles spread within the pulmonary arterial system and cause inflammatory reactions. They also induce the development of typical myointimal proliferative lesions which gradually reduce the lumen of small pulmonary arteries, leading to pulmonary hypertension. Endothelial damage, with thrombosis and thromboembolism, has sometimes been reported. Chronic infections eventually lead to insufficiency of the right heart, which results in passive congestion of the liver, spleen, and lungs, ascites, and peripheral edema. The onset of clinical signs of dirofilariasis is insidious and may go unrecognized until substantial vascular damage has occurred. A deep, usually soft chest cough is a common early sign. Coughing may be aggravated by exercise, severe coughing being sometimes accompanied by hemoptysis, a sign highly suggestive of heartworm infection. In the late stages some dogs display characteristic respiratory movements: the rib cage remains expanded, and there is an extra inspiratory effort. The very poor exercise tolerance is a consistent clinical finding in advanced cases. Dogs which are suddenly forced to exercise may rapidly become ataxic or experience syncope. Emaciation develops gradually. The final stage of congestive failure of the right heart is only seen in a small proportion of affected dogs. A relative infrequent complication of *D. immitis* heavy infestations is the occurrence of pulmonary embolism by adult worms – or worms killed by chemotherapy – which occlude small pulmonary arteries and cause infarction. Also described in very heavy infections is the “liver failure syndrome” caused by worms which have invaded the vena cava and hepatic veins. The cause of the distribution is not known, but it may be related to overcrowding in the normal pulmonary arterial habitat. The syndrome is characterized by sudden onset of weakness, anorexia, ► bilirubinuria,

hemoglobinuria, hemoglobinemia, and ► [anemia](#). The anemia develops due to disseminated intravascular coagulation and fragmentation of red cells. Azotemia develops, and death usually occurs in 1–3 days. Another possible complication of *Dirofilaria* infection is ► [immune complex glomerulonephritis](#). Adult worms produce larvae (microfilaria) which dwell in small vessels and are infectious for blood-sucking mosquitoes. ► [Microfilariae](#) are usually of little consequence for the dog. If microfilariae block the arterioles of the skin, there is ► [erythema](#), ► [pruritus](#), and loss of hair. This effect may however be due to concurrent dipetalomiasis (for reasons of uniformity, see dirofilariasis, etc.). Infections with *D. immitis* have also been reported in the cat, wild Canidae and Felidae, and rarely in humans.

Onchocerca armillata and *Elaeophora schneideri* are another two filarial parasite species which live in large blood vessels, produce microfilariae, and have biting insects as obligate intermediate hosts. *O. armillata* is focally highly prevalent in ruminants in Africa and Asia. In cattle it produces striking lesions in the intima and media of the thoracic aorta: tunnels, ► [nodules](#), roughening, and calcifications. However, the only cardiovascular disturbances that have been reported appear to be slight aneurysmal changes, despite the presence in the aortic wall of worms which may be up to 70 cm long. Other symptoms such as repetitive episodes of collapse and tetanic convulsions, periodic ophthalmic impairment, and even blindness sometimes observed in heavily infected animals have been attributed to the microfilariae. *E. schneideri* is common in wild ruminants and sheep in Northern America. The adult worms live in the cephalic arteries of the host, while microfilariae are found in the skin, mainly in the head region. In elk and moose, the infection often causes inflammatory reactions and thrombosis of the cephalic arteries, which may lead to obstruction and ischemic necrosis. The disease, if not fatal, may induce various neurologic signs such as blindness and necrotizing lesions in the skin of the head. In sheep, arterial

lesions are minimal or absent, but hypersensitivity to microfilariae often results in severe exudative dermatitis, primarily over the head.

Angiostrongylus vasorum and *Aelurostrongylus abstrusus* are small metastrongyle worms. The adult *A. vasorum* lives in the pulmonary artery and right ventricle of the dog where it causes a proliferative endarteritis and thrombosis in pulmonary arteries comparable to that induced by *D. immitis*. *A. abstrusus* is a lungworm of cats. In addition to causing pulmonary nodules, it is believed to incite the smooth muscle hypertrophy and medial ► [hyperplasia](#) of the pulmonary arteries which may focally be observed in up to 70 % of cats. The respiratory clinical signs of these two infections are described in Respiratory System Diseases, Horses, Swine, Carnivores.

The spiruroid worm *Spirocerca lupi* is primarily a parasite of dogs. The major clinical signs of spirocercosis are associated with the presence of adult worms in the esophagus. They are described in ► [Alimentary System Diseases, Carnivores](#). However, significant lesions are also caused by the migrating larvae which spend about 3 months in the adventitia and media of the aorta. Aortic lesions include the formation of small nodules containing larvae, thickening of the intima and media, and deposition of atheromatous plaques. Weakness of the aortic wall and partial rupture of the layers sometimes leads to the development of shallow aneurysmal pouches, with possible rupture, and fatal hemorrhage. In most cases, aortic lesions do not produce any clinical signs.

Veins

Schistosomes are important parasites of the venous vascular system of vertebrates (Table 2). In Africa, *Schistosoma bovis*, *S. matthei*, and *S. curassoni* occur commonly in ruminants, and *S. rhodhaini* has been reported to infect dogs. In Asia, *S. indicum*, *S. spindale*, and *S. nasale* occur in a variety of domesticated animals including cattle, water buffalo, sheep, goat, and horse. *S. incognitum* has been reported in pigs, dogs,

sheep, goats, and occasionally cattle. ► *S. japonicum* is an important zoonosis in South-east Asia. In China, dogs, goats, rabbits, cattle, sheep, pigs, horses, and water buffaloes have all been found to harbor the infection (► [Schistosomosis](#), [Animals](#)). Infection by schistosomatid worms (species of the genera *Trichobilharzia*, *Bilharziella*) is quite common in water birds and is related to temporary cutaneous (allergic) lesions in man after zoonotic transmission. All these parasites live in the mesenteric and hepatic veins of the host, except for *S. nasale* which is found in the veins of the nasal tissue. The presence of adult worms in the veins does not induce reactions from the host, except when dead worms are occasionally blocked into small veins of the intestine or swept into the liver where they give rise to focal inflammatory reactions (phlebitis) and lymphoid nodules. The pathogenesis of schistosome infection is mainly caused by the migration of eggs through the intestinal wall and their accumulation in the liver and other organs. These clinical syndromes are discussed under ► [Alimentary System Diseases](#), [Ruminants](#).

Lymphatic Vessels

Filariid worms of the genus ► *Brugia* parasitize the lymphatic system of dogs and cats in tropical areas. They do not usually cause lymphedema and elephantiasis as in humans. *Dracunculus insignis* may occasionally infect dogs in North America, causing obstruction and inflammation of the lymphatic vessels, leading to lymphedema.

Carrion's Disease

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

This disease honors the fatal self-infection of the Peruvian physician **Daniel A. Carrion**

(1850–1885) by injection of *Bartonella bacilliformis*. This bacterium, which may introduce in South America the so-called hemorrhagic ► *Oroya* fever as severe symptom of the bartonellosis, is transmitted by ► *sandflies* (= genera *Lutzomyia*, *Phlebotomus*). Apparently these agents of disease enter the eggs in the female's ovaries so that many insects of the next generation are already infected. If the disease is survived, the host's skin often shows inflamed protruding pustules (black warts), which together are described as ► *Verruga peruana* (Latin: *verruca* = wart).

Caryocyst

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Caryocyst is a characteristic ► *tissue cyst* of ► *Caryospora* species, which contains only a single parasite as waiting stage.

Caryophyllaeus laticeps

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Classification

Monozoic tapeworm belonging to the group ► *Eucestoda* in ► *Cestodes* (► *Amphilina foliaceae*).

Morphology

Diagrammatic representation of the adult monozoic tapeworm ► *Caryophyllaeus laticeps* (3 cm long) from the intestine of cyprinid and castomid fish; intermediate hosts are possible (Fig. 1).

AH = adhesion zone; DB = dense bodies in the vitelline system; GA = genital atrium (joint pore of UT and VE); OV = ovary; TE = testis; UT = uterus; VD = vas deferens; VE = vas efferens; VG = vagina; VI = vitelline glands; Z = interruption (animals are longer).

Name

Greek: *karyon* = nucleus; *phyllon* = leaf.

This monozoic (without proglottids) primitive tapeworm belongs like ► *Archigetes sieboldi* to the order Caryophyllidae, the members of which

Caryophyllaeus laticeps, Fig. 1 *Caryophyllaeus laticeps*

are intestinal parasites of fish in freshwater. These species are distributed worldwide. They are characterized by a lacking internal or external segmentation, by the fact that they possess only a single set of male and female sexual organs, and that they do not develop true suckers but only groove-like adhesion zones at the apical pole (Fig. 1). The life cycle is similar to those of ► *Archigetes* and ► *Amphilina* species.

Caryophyllaeus Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *karyon* = nucleus; *phyllon* = leaf. Latin: *laticeps* = broad top. English: carnation worm of fish.

Caryophyllaeus Species, Fig. 1 Scanning electron micrograph of the typical anterior systems of folds of the armed (a) and unarmed scolices (e.g., adult *Caryophyllaeus* worm), HK hook

General Information

The species *Caryophyllaeus laticeps* and *C. fimbriceps* are so-called monozoic tapeworms which reach as adults a length of about 3–5 cm containing only a single set of female and male sexual organs (see Fig. 1 ► [Caryophyllaeus laticeps](#)). The anterior end is provided with an adhesion system that has foldings leading to the name-giving aspect of a carnation flower as can be seen in the scanning electron micrograph (Fig. 1b, c). These worms live attached at the intestinal worms of catostomid and cyprinid fish. The 75 µm long eggs are discharged with the feces of its host. At this time they already contain a 10-hooks miracidium larva, which is ingested by intermediate hosts belonging to soil-inhabiting annelid worms of the *Tubifex* group. Inside these intermediate hosts, a so-called **proceroid larva** is developed within 1–4 months (depending on the outer temperatures). The development occurs inside the coelom of the intermediate hosts. If fish feed such infected *Tubifex* worms, the proceroid larva develops into the adult stage within 1–3 months. The adults live about 3–4 months and are then discharged with the feces. Inside aquaria systems, fish may bear large amounts of such parasites, which endanger the health and life of their hosts considerably.

Symptoms of Disease

Attached worms may introduce catharralic-hemorrhagic inflammations. Larger amounts of such parasites may block the intestine, reduce the food uptake, and thus lead to such a loss of weight that the fish appear with depressed flanks or may even die.

Infection

Oral uptake of infected *Tubifex* worms.

Diagnosis

Microscopical determination of the typical eggs containing the 10-hooks-larva.

Prophylaxis

Avoid feeding of fish with living *Tubifex* worms but use deep-frozen worms.

Treatment

Use the product Tremazol[®] of Fa. Sera being based on praziquantel.

Genus of ► [Coccidia](#).

Life Cycle

See Figs. 1, 2, and 3.

Caryospora Species, Fig. 1 Life cycle of *Caryospora bigenetica* (according to C. Sunderman). **A** First type of final host (rattlesnake). 1 The sporulated ► oocyst contains a single ► sporocyst with 8 sporozoites. 2–4 After oral infection with oocysts two generations of schizonts are formed inside the intestinal epithelium. 5/6 Male and female gamonts are formed and later gametes occur. The male ► gamont (G) forms numerous gametes. 7/8 After fertilization, a thick-walled oocyst is formed inside the host cell and becomes free within the feces. While sporulating on the ground a single sporocyst with eight sporozoites is formed inside each oocyst. **B** Second type of final host (mice, cotton

rats, dogs). 2.1–2.4 Repetition of the schizogonic and gamogonic development (described in 1–8). The ► sporulation of oocysts may occur in skin regions (2.4). 2.5 Sporozoites that were set free from their sporocysts while still inside the skin of their hosts enter other host cells and induce formation of so-called caryocysts, i.e., cells being surrounded by fibrillar material. Those caryocysts are infectious for both host types (if taken up orally). Furthermore these caryocysts are infectious for hosts of the second type during close skin contacts. CA ► caryocyst, FI filamentous material, HC host cell, ME ► merozoite, OO ► oocyst, OW oocyst wall, PV ► parasitophorous vacuole, S ► sporozoite

 sporulated (*right*) oocyst

Caryospora Species, Fig. 3 Light micrograph of a cluster of free sporocysts of *C. bigenetica* each containing eight sporozoites. These sporozoites hatch still in the skin and enter epithelial cells, and so skin my show large damaged regions. By the skin-to-skin contact the oocysts and/or free sporozoites may be transmitted, too

Caryospora Species of Falcons

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name

Greek: *karyon* = nut = nucleus; *sporos* = seed.

Caryospora cherrughi oocysts are found in the feces of the saker falcon *Falco cherrug* in Saudi Arabia. It is the third species seen in *F. cherrug*. The oocysts measure $32.1 \times 29.3 \mu\text{m}$ and contain each a sporocyst of $24.1 \times 19.6 \mu\text{m}$ in size. The sporocysts do not possess a stieda body. Other species of *Caryospora* in falcons are shown in the following list (Table 1).

Casinaria texana

Ichneumonid insect used for biological control of pests.

Castration

Some parasites castrate their hosts due to chemical or mechanical measurements, e.g., the digeneans *Parorchis* and *Zoogonus* do it in their intermediate hosts (= snails), see ► [Behavior](#).

Castellani, Aldo, Sir (1874–1971)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Born in Florence, Italy. He studied in Bonn (Germany) and in London (UK) and detected 1903 in Uganda cases of sleeping sickness. In Ceylon he detected the agent of framboesia (*Treponema pallidum pertenue*). Furthermore the species ► [Acanthamoeba castellanii](#) was named honouring his first descriptions. Together with Albert Chalmers he published the standard book, *Manual of Tropical Medicine*.

Catatropis hatcheri

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species lives besides *C. chilinae* in galliformes and anseriformes birds (house chicken, ducks) in South America. Intermediate hosts are pulmonate and prosobranch snails, while their emerged cercariae encyst in the environment on vegetation. The adult worms measure

2.5 × 0.9 mm (in mean), are elongate with attenuated anterior and rounded posterior ends, and appear ventrally concave. Their dorsal surface is smooth, while the ventral side is covered with scales. Only an oral sucker is formed (0.12 × 0.14 mm) being subterminally located. The eggs appear oval, are provided with an operculum, and measure 19–24 × 10–12 µm. The trioculated cercariae have a mean size of 336 × 130 µm.

Therapy

Praziquantel.

Catatropis verrucosa

This species (1–6 × 0.7–2 mm), which has no ventral sucker, lives in the caeca of ducks and other waterbirds. The eggs show polar filaments. High infection rates may introduce ulcerative typhlitis. Common in Europe, Africa, Asia, and North America.

Cathaemacia cabrerai

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Trematode species which also infects humans.

CD36 Gene

Polymorphism of this gene is often linked to a high susceptibility to severe malaria. Similar effects are described due to polymorphism of the genes of the TNF – λ promotor or the genes for the interferon receptor I.

CD4+ Cells

Memory cells, CT-helper-cells, which inform upon an infection the B-lymphatic system to produce antibodies.

CDC

Centers for Disease Control and Prevention.

CDPKs

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Calcium dependent protein kinases are probably involved in the regulation of invasion and egress from host cells in protozoan parasites. While CDPKs are absent in vertebrates, they might be probable targets for pharmaceutical intervention. Such kinases are well characterized in ► *Toxoplasma gondii* (TgCDPK1) and *Plasmodium falciparum* (PfCDPK1).

Celation

From Latin: *celatio* = secrecy. Phase of virus inside insect vector, during which a transmission is not possible.

Cell

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Cells are the basic units of life. It was recognized by Virchow in 1855 that they are the smallest

units capable of maintaining the continuity of life or, as he expressed it, *Omnis cellula e cellula* (every cell derives from a cell). Organic matter on earth exists in the following forms: various types of cells, short sequences of stable proteins (► [Prions](#)), extracellular genomes (viroids or naked RNA molecules), and protein capsules, or capsids, containing relatively short molecules of DNA or RNA often surrounded by an additional membrane (bacteriophages and viruses). Prions, viroids, phages, and viruses lack their own metabolism and the ability to reproduce independently, whereas all types of cells are true living systems with metabolic ability (► [metabolism](#)) and the capacity for independent reproduction (► [cell multiplication](#)). All cells share the following attributes:

- They are enclosed by a ► [cell membrane](#) (Fig. 1); some are motile (Fig. 2).

Cell, Fig. 1 Fine structure of a typical eukaryotic cell: (a) cross section of the free flagellum, (b) cross section of the basal body. *B* basal body, *CT* cytoplasm, *EN* endocytosis, *EX* exocytosis, *F* flagellum, *GO* Golgi apparatus, *H* heterochromatin, *L* lipid, *LY* secondary lysosome (phagolysosome), *ME* cell membrane (plus surface coat), *MI* mitochondrion, *MU* multivesicular body, *N* nucleus, *NU* nucleolus, *NV* food vacuole (endocytotic vacuole), *PE* perinuclear space, *PL* primary lysosomes, *PO* polyribosomes (chains), *PP* peroxisome with protein crystal, *RER* rough endoplasmic reticulum, *RI* ribosome, *SER* smooth endoplasmic reticulum

Cell, Fig. 2 Amebic movement brought about by a steady forward flux of the central liquid endoplasm and its transformation into a more stable form as it moves posteriorly and laterally. The origin of the forces needed for such movement is explained by either apical (a) or posterior

(b) contractions (arrows). *A* Zone of adhesion to the surface, *EC* hyaline ectoplasm, *EN* dense, granulosomatous endoplasm, *F* fluid portion of endoplasm, *N* nucleus, *S* stable, nonfluid portion of endoplasm

Cell, Fig. 3 Nuclear pores (diameter c. 80 nm): (a) Surface view showing the eight outer peripheral annuli; (b) longitudinal section of an active pore. (c) Longitudinal section of an inactive pore. *A* annular element, *AM* amorphous material, *C* center channel

(diameter 15–20 nm) also called central granulum when RNA passes through, *CY* cytoplasm, *D* diaphragm, *FI* filamentous layer, *FL* filaments connected at inner annular elements, *H* heterochromatin, *N* nucleoplasm (karyoplasm), *PE* perinuclear spore, *R* RNA, *RI* ribosome

- Their systems of reproduction use DNA for information storage and RNA for directing cellular organization.
- Their genomes may undergo accidental change (i.e., they mutate).
- They can use chemical bond energy or light energy (autotrophic organisms) to run their metabolic systems.

- They can detect and respond to environmental signals, and they can receive, recognize, and transmit signals and impulses.

They may also be motile and, in the case of eukaryotes, may have a flowing ► [cytoplasm](#) (Fig. 3). Two basic types of true cells are distinguishable: ► [prokaryotes](#) and eukaryotes. There

are no transitional forms in existence today, and thus these two forms are quite distinct.

Cell Anus

Synonyms

Cytopye

Definition

Special place for ► [exocytosis](#) developed by many ► [protozoa](#).

Cell Junctions

Membrane-bound structures exist that mediate the joining of cells. These are needed for fusion of gametes and similar structures and are also found at places where ► [flagella](#) are attached to the surfaces of ► [protozoa](#). The undulating membranes and recurrent flagella of trypanosomes and ► [trichomonads](#) are joined to the cell by means of such cell junctions. Cell junctions also play a role in the attachment of many parasites to the surfaces of host cells. For example, trypanosomes use junctions for attachment to the vector's intestine. Another example is the ► [moving junction](#) that is formed during cell penetration of Apicomplexa (► [Apicomplexa](#)/Fig. 8).

Cell Membrane

Synonyms

Unit membrane; plasmalemma.

General Information

All cells are surrounded by a 5–10 nm thick cell membrane (► [Pellicle](#), Fig. 1G, ► [Surface Coat](#), Fig. 2). In living cells this membrane always forms a closed sac or vesicle. The membrane is composed of species-specific amounts of various proteins and a double layer of lipids. It is physiologically and morphologically asymmetric, presenting a p face (directed towards the ► [cytoplasm](#)) and an external e face. High magnification electron microscopy reveals that it is composed of three layers (trilaminar) (► [Pellicle](#), Fig. 1G). It is semipermeable, i.e., only certain types of molecules may cross it. Several models have been created to explain how this biomembrane functions. The most widely accepted is the fluid mosaic model of Singer and Nicolson in which it is proposed that the membrane consists of a double layer of lipid molecules within which proteins and other components float like icebergs. At least some of the proteins may be structured to form pores. The membranes expand by additive inclusion of vesicles formed inside the cytoplasm and shrink by formation of endocytotic vesicles. The functions of the cell membrane are various and include transport processes such as uptake (► [Membrane Transport](#), ► [Endocytosis](#)), ► [secretion](#) of substances, cell recognition, and joining of cells (► [Cell Junctions](#)).

Cell Multiplication

In the ► [Protozoa](#) different ways of cell multiplication have been developed during phylogeny.

Binary Fission

The most basic type of multiplication is ► [binary fission](#), which always produces two daughter cells and needs a preceding duplication of the organelles of the mother cell (Figs. 1 and 2). Since the axis of cell division is fixed in the different groups within the Protozoa different types can be distinguished:

Cell Multiplication, Fig. 1 (a–f) Diagrammatic representation of different types of binary fission (invaginations are shown by *small arrows*). (a) Ameba type: division without fixed axis. (b) Trypanosomatid type (here ▶ *Leishmania*): longitudinal division. (c) Trichomonad type (here *T. vaginalis*, note that it is only a longitudinal division at the beginning). (d) Endodyogeny of tissue-cyst-forming coccidia (e.g., *Toxoplasma*, ▶ *Sarcocystis*): inner

development of daughter cells. (e) Ciliata type (e.g., *Balantidium*): cross-division. (f) Opalina type: oblique division. AF ▶ anterior free flagellum, AX ▶ axostyle, B ▶ basal body of flagellum, CI ▶ cilium, CY ▶ cytopharynx, DC ▶ daughter cell, F ▶ short flagellum in a pocket, KI ▶ kinetoplast, MA ▶ macronucleus, MC ▶ mother cell, MI ▶ micronucleus, MN ▶ micronemes, N ▶ nucleus, PS ▶ pale pseudopodium, RF ▶ recurrent flagellum, RH ▶ rhoptries

- Irregular division. In microsporidians (e.g., *Nosema*, cf. life cycles) binary fissions occur after nuclear divisions. In these cases the ▶ **cytoplasm** is divided irregularly and different-sized

daughter cells are formed, which, however, obtain a similar shape after feeding.

- Amoeba-like division (Fig. 1a). In rhizopods (e.g., ▶ *Entamoeba histolytica*,

Cell Multiplication, Fig. 2 (a–c) Binary longitudinal divisions in trypanosomes (a, b transmission electron micrographs; c light micrograph). (a) ▶ *Blastocrithidia triatomae*; note that the basal bodies of the flagella (F1, F2) and the nuclei are already divided. ×24.000. (b) *Trypanosoma vivax*; trypomastigote from blood during reduplication of the

kinetoplast. ×22.000. (c) *Crithidia* sp. from cultures; late binary fission. ×1200. B basal body of flagellum, CR chromatin, DB ▶ dense bodies, DK dividing kinetoplast, F flagellum, K ▶ kinetoplast, MI mitochondrion, N nucleus, NU ▶ nucleolus, OM outer surface (▶ Cell Membrane), PR ▶ paraxial rod of flagellum, ST ▶ subpellicular microtubules

Acanthamoeba) the cell division is more or less irregular with respect to the cytoplasm; however, the constriction always occurs perpendicular to the spindle axis.

- Longitudinal division (Fig. 1b–d). In flagellates (e.g., diplomonads, ▶ trichomonads,

trypanosomatids) and sporozoans (e.g., ▶ Coccidia) the axis of binary cell division runs longitudinally. Flagellates determine the polarity of the division axis by the initial duplication of the ▶ basal bodies of the ▶ flagella (Fig. 2). Binary fission is found in only a few

species of the ► **Sporozoa**, e.g., blood merozoites of ► **piroplasms** divide in this way. A peculiar longitudinal division is the ► **endodyogeny** of those ► **coccidia** that form tissue cysts (Figs. 1d and 4). Inside a mother cell two daughter cells are formed arching over the two angles of the dividing nucleus. The daughter cells produce their inner two pellicular membranes de novo (using membranes of the ► **endoplasmatic reticulum**) and take over the outer membrane of the mother cell's ► **pellicle**; the two inner ones disintegrate (Fig. 5a). In ► **trichomonads** the axis of all cell divisions is longitudinal, but only at the beginning (Fig. 1c) when the flagellar basal bodies and the nucleus are reduplicated; later on the divided nuclei wander below the surface membrane into opposite positions, and finally an oblique or even transverse cytoplasmic division appears (Fig. 1c).

- Oblique division (Fig. 1f). In opalinids (see life cycles), which are characterized by oblique rows of ► **cilia**, binary fission occurs during the sexual and asexual developmental phases. The axis of the cytoplasmic division initially runs longitudinally, but soon becomes parallel to the oblique rows of cilia. It is thus intermediate between the longitudinal fission of flagellates and the transverse division of ciliates.
- Transverse (cross) divisions (Fig. 1e). In ciliates (e. g., ► **Balantidium**, ► **Ichthyophthirius**) binary fission starts with the duplication of the cytostomal kinetosomes (basal bodies) and is followed by the division of the ► **macronucleus** and ► **micronucleus**. The axis of cytoplasmic division runs perpendicular to the axis of the nuclear spindles (Fig. 1e); cell constriction may occur simultaneously or with some time lag. Since this division proceeds across the rows of cilia, it is also described as homothetogenic fission.

Rosette-Like Multiplication

If there is incomplete or delayed division of the cytoplasm the newly formed nuclei may initiate a new division, thus giving rise to a more or less simultaneous development of more than two parasitic protozoans that remain attached at their

Cell Multiplication, Fig. 3 SEM-micrograph of a cluster of cultured ► **promastigotes** of ► **Leishmania major** being closely tied with their flagellum. This stage – in light microscope – may be kept for a rosette-like developing stage. ×3000

posterior poles. This may be repeated and the whole bulk appears as a ► **rosette**; under light microscopy this was misinterpreted as a stage of multiple division. Such rosettes are frequently found in trichomonads and trypanosomes (especially in cultured forms), and are also relatively common in ► **Toxoplasma gondii** during the acute phase of infection when endodyogenies are often repeated inside ► **parasitophorous vacuoles** of macrophages and reticuloendothelial cells. However, in cultures of trypanosomatids most of the rosette-like stages are artefacts, while during movements they became irreversibly tied with their flagella (Fig. 3).

Multiple Divisions

Multiple divisions are characteristic of amebae, sporozoans, and ► **microsporidia**, but are rarely observed in the other parasitic protozoan groups. The formation of daughter cells may be initiated by three main types of mother cells.

- Multinuclear type. Daughter-cell formation starts at the end of a phase of repeated nuclear divisions (Figs. 3, 4b, and 5b). In this way multinucleate plasmodia occur (Fig. 4a–c), which for example led to the naming of the

Cell Multiplication, Fig. 4 (a–f) Diagrammatic representation of multiple divisions. (a) *Amoeba* spp.; formation of vegetative stages after excystation. (b) Formation of merozoites by schizonts of species of *Eimeria*, *Plasmodium*, *Theileria*, etc. (c) Formation of microgametes, e.g., *Eimeria* spp. (d) Formation of microgametes of *Plasmodium* spp. and other hemosporidia (e.g., “exflagellation”). (e) *Sarcocystis* spp.; formation of merozoites by schizonts (1) and of microgametes by microgamonts (2). (f) Formation of cytomeres. These may each develop: (1) 2 merozoites

(some *Eimeria* spp.) (2) a single kinete (*Babesia* spp.) (3) many parasitic stages of the life cycle of various coccidians, i.e., merozoites of *Glomerulus* spp. or sporozoites of species of *Plasmodium*, *Babesia*, and *Theileria*. (b) ▶ **Schizogony** (ectotype) or ▶ **sporogony** along the surface of cytomeres (or sporonts) as found in many Coccidia (e.g.,

Eimeria, *Globidium*, *Plasmodium*, *Theileria*, *Babesia*). (c) Endopolygeny (e.g., schizonts of *Sarcocystis* spp.) produce the daughter cells at once around the lobulated giant nucleus. DC daughter-cell anlage, N nucleus, PN polymorphous (polyploid) giant nucleus

genus ▶ *Plasmodium*. Such multinucleate stages are found in the life cycles of ▶ *Entamoeba histolytica*, in schizonts and sporonts of ▶ *gregarines* and of some coccidia (Figs. 4b, 5b, 6, and 7), in all gamonts of gregarines, but only in microgamonts of some coccidia (e.g., Fig. 3c), and in some developmental stages of

myxosporidia. In these cases the cytoplasm may be divided evenly or not (but always in a species-specific pattern). In eimerian and theilerian schizonts (Fig. 4b), and in sporonts of hemosporidia and of some piroplasms, daughter-cell formation is connected with the last ▶ **nuclear division**, thus giving rise to

Cell Multiplication, Fig. 6 Asexual reproduction in coccidian blood parasites – TEM-micrograph of a section through a lymphoblastic cattle cell containing directly in the cytoplasm a macro- and a microschizont (i.e., Koch's bodies) of the piroplasma parasite ► *Theileria annulata*. The macroshizont is cut during the phase of nuclear

reproduction – the microschizont during formation of merozoites at the periphery. $\times 8000$. DM developing merozoite, HC host cell cytoplasm, MIH mitochondrion of the host cell, N nucleus, RN residual nucleus, SCK macroshizont, SCM microschizont

endodyogeny-like features (Fig. 5a) when producing merozoites or sporozoites. In eimerian microgamonts in general a single microgamete is formed from each nucleus (leaving, however, an electron lucent remnant of the karyoplasm). Only occasionally do two ► **microgametes** originate from such a microgamont's nucleus.

- Uninuclear type. Daughter-cell formation starts without a preceding phase of nuclear divisions. However, in most cases the nucleus of the parasitic stage has grown considerably and is provided with a lobulated surface (Figs. 4d, e and 5c). During the final division of this eventual giant nucleus, daughter-cell formation takes place simultaneously, incorporating portions of the nucleus, the chromosomal components of which had apparently

been increased by preceding endomitosis. Such a splitting process occurs during the ► **schizogony** of ► **sarcosporidia** (Fig. 5c) and has been described as endopolygony. The microgamonts of some *Sarcocystis* spp. and of *Plasmodium* spp. produce their microgametes in this way (Fig. 4d, e). A similar simultaneous process is found in sporonts of some piroplasms during the mass production of sporozoites.

- Intermediate type (Fig. 4f). In these cases a large mother cell with a lobated giant nucleus is divided into numerous uninuclear cytomeres; the single limiting membrane of these stages originates from the surface membrane of the original cell or from the endoplasmic reticulum. Such cytomeres are regularly formed in schizonts of some

Cell Multiplication, Fig. 7 (a–c) Asexual reproduction by endopolygony in *Sarcocystis arieticanis* schizonts (from sheep). Montpellier, France

General Information

When a parasite comes into contact with a potential host cell, two series of events may occur which lead to intracellular parasitism: first comes a recognition step which enables a suitable close association between both partners and then second comes the internalization of the organism within the host cell. The mechanisms of recognition are far from being entirely elucidated, as well as the ones by which entry occurs. Data have been obtained however, which show that the different parasite groups have evolved different strategies toward these goals.

A major question when dealing with host cell invasion by a pathogen is to decide whether this one actively enters a cell or whether it is engulfed by the process called phagocytosis. The matter is rather clear with those parasites which force their way through the plasma membrane of the host cell or fuse their membrane with it; it is more confusing when internalization occurs within a parasitophorous vacuole, the membrane of which is continuous with the host cell plasmalemma during the whole invasion process, as is the case with most protozoan parasites. Moreover, when a parasite uses phagocytosis to gain access into a cell, another important issue is its behavior facing the fate of a phagosome, i.e., fusion with a lysosome and exposure to a cocktail of lytic enzymes which are supposed to digest the phagosomal contents. Parasites seem to have also evolved various ways of escaping this fatal outcome, as will be described below. Different invasion processes which occur among intracellular eukaryotic pathogens are depicted in Fig. 1.

Cell Penetration, Fig. 1 Invasion processes observed among different intracellular pathogens. 1 Invasion by phagocytosis, parasite development in phagolysosomes (e.g., *Leishmania* spp.). 2 Invasion by “phagocytosis,” escape of the parasite into the host cell cytoplasm (e.g., *Trypanosoma cruzi*). 3, 4 Active invasion of Apicomplexa, characterized by a moving junction and the development of the parasitophorous vacuole. An originality of piroplasms (e.g., *Babesia*, *Theileria*) is the disintegration of the parasitophorous vacuole membrane soon after invasion, the parasite then lying directly within the cell cytosol erythrocytic stroma (3). Other Apicomplexa complete their schizogony within a parasitophorous vacuole that does not fuse with lysosomes (4). 5 Invasion through the host cell plasmalemma (Microsporidia)

Because of their medical interest, host cell invasion by apicomplexan zoites (e.g., *Plasmodium*, *Toxoplasma*, *Eimeria*, *Sarcocystis*, or piroplasms) has been studied to a great extent (Apicomplexa/host cell invasion).

In contrast, little morphological data are available on the invasion of host cells by kinetoplastids. More studies deal with the ways these organisms escape the phagosome lysosome fusion (*Trypanosoma*/host cell invasion,

Leishmania/host cell invasion). Although rather poorly known, the mechanism of cell invasion by Microsporidia has very peculiar characteristics. Microsporidia self-inject into their host cell by devaginating a membranous organelle (polar tube) which forces its way through the host cell plasmalemma and through which the parasite cytoplasm moves into the recipient cell (Fig. 1). Invasion is thus intrusive: this is the only case known among intracellular parasitic protozoa where parasite development may occur either in the cytoplasm of the cell or within a parasitophorous vacuole, but whether this vacuole forms at invasion or later is not known.

Apicomplexa Invasion

Host Cell Recognition

Regarding the host cell recognition process, two groups seem to exist among Apicomplexa: one in which a highly specific recognition step occurs which concerns the blood parasites (Hemosporidia, Piroplasms) and another in which little if any specific recognition of the host cell can be demonstrated, concerning the Coccidia. This difference is better understood when one realizes that a *Plasmodium* merozoite is only able to invade the red blood cells of an extremely narrow range of hosts, whereas a *T. gondii* tachyzoite readily invades almost any type of cells it gets in contact with. The difference between the two groups could also be interpreted as the need for receptor-ligand-mediated adhesion as a prerequisite to invasion by blood parasites, whereas this step would be unnecessary to Coccidia whose host cell and tissue specificity in situ could be due to other mechanisms. However, another possibility is that binding always occurs before invasion, but its specificity varies depending on the parasite and allows a variable range of invasion that may or may not need further specific interaction to determine development or escape and search for a more suitable host cell.

Although the surface proteins of the invasive stages seem to be involved in the recognition binding to the host cell, the microneme's proteins which are translocated on the surface of the parasite appear to be essential in parasite-host cell interaction in all Apicomplexa. The present status of knowledge does not clearly differentiate between recognition binding and motility of Apicomplexan zoites.

In the case of blood parasites (*Plasmodium*, *Babesia*), receptor-ligand types of interaction have been shown to occur between zoites and erythrocytes. These events seem to be involved in the adhesion of the parasite to its target cell which holds the partners together after accidental contact and allows invasion to proceed. Phase contrast microscopic observations of red blood cell invasion by merozoites of *P. knowlesi* or *P. falciparum* have shown that initial contact could occur between any two points of the surfaces of the two cells. Then the merozoite reorients itself in such a way that its apical end faces the erythrocyte membrane. Moving junction formation and invasion then occur. Reorientation has been suggested to be effected by a gradient of receptors directed toward the apical end of the zoite. The respective part of receptor-mediated interaction in initial contact, reorientation, and moving junction formation is still unclear because of the difficulty of manipulating these different events in vitro. Thus, the following applies to these interactions as a whole, and we will only describe the *P. falciparum* model.

Recognition events concern interactions between merozoite receptors and erythrocytic ligands. Soluble molecules acting as bridges between both surfaces may also be involved. Most of the data obtained on these interactions come from in vitro experiments in which a *P. falciparum* culture was subjected to various treatments (use of variant red cell phenotypes, enzymatic alteration of erythrocyte surface, competition with soluble molecules) or from affinity of parasite molecules for erythrocytes

(erythrocyte-binding antigens) or erythrocyte fractions (glycophorin).

Concerning the erythrocyte, glycophorin A (major sialoglycoprotein) is the major ligand in interaction with merozoites. More precisely, O-linked sialylated polysaccharides of the molecule seem to be directly involved in recognition. However, in addition, sialic acid-independent recognition and invasion can occur in certain strains, which suggests the existence of alternate pathways allowing the parasite to survive if one way fails to operate.

The main merozoite receptors described so far are molecules having affinity for the erythrocyte surface that were initially described as erythrocyte-binding antigens (EBA). These molecules are located in micronemes and are translocated in a transmembrane orientation on the merozoite surface where they play a major role in host cell recognition-invasion. A highly conserved family of EBA proteins expressed in the merozoite stages of various *Plasmodium* has been characterized; they all contain a conserved N-terminal cysteine-rich domain that is involved in recognition. As for most microneme proteins, the way these proteins stored in the lumen of an organelle become transmembrane in the parasite surface is unknown.

Although *P. knowlesi* shares a part of its erythrocyte host range with *P. falciparum*, the recognition events seem to be distinct from the ones involved for the latter species. The Duffy blood group antigen has been described to play a key role in *P. knowlesi* invasion, in association with the DBL, which is a member of the erythrocyte-binding ligands EBL. The Duffy antigen is also involved in *P. vivax* invasion.

The role of merozoite surface proteins in erythrocyte invasion is unclear; the major merozoite surface protein (MSP1) may participate in initial binding, and antibodies inhibiting its proteolytic cleavage during invasion block cell entry, but the receptor for this interaction is unknown. This surface protein may be acting as an early ligand of low affinity that allows close contact between

both partners and is then strengthened by the EBL-glycophorin interaction.

Whether the receptor-ligand recognition that precedes invasion is maintained in the moving junction that powers invasion is unknown; however, observations on the interaction between *P. knowlesi* and Duffy negative red cells where the junction does not form suggest that the DBL protein may be involved in the junction.

In the sporozoite stage of the malarial parasite life cycle, receptor-ligand recognition has been postulated to drive the interaction with the target cell, which is the hepatocyte. Although *Plasmodium* sporozoites have been shown to invade a rather large range of cells in vitro, their very efficient homing to the hepatocytes in vivo is probably driven by the affinity between the circumsporozoite surface protein CSP and the hepatocyte surface heparan sulfate proteoglycans.

Another system of recognition, which is found in *Plasmodium* sporozoites and is conserved in many Apicomplexa, is the TRAP microneme protein family. In *Plasmodium* sporozoites, this protein also binds sulfated sugar-containing domains on the hepatocyte surface. *Toxoplasma gondii* and *Eimeria tenella* contain TRAP-like proteins in their micronemes, but their putative receptors have not been identified.

Micronemes of *T. gondii*, *Cryptosporidium*, and *Sarcocystis* also contain proteins with cell-binding properties, some of which have lectin features that probably play a role in host cell recognition, although yet unidentified.

Host Cell Invasion

Due to their medical significance, host cell invasion by Apicomplexan zoites has mainly been studied with malaria parasites and *T. gondii* to a lesser extent with the Coccidia and *Eimeria* and *Sarcocystis* or with piroplasms.

In all cases in which invasion has been described in detail, Apicomplexan zoites enter the host cell apical end first, i.e., the area where the so-called apical complex is located and

especially where the rhoptry ducts reach the zoite membrane. The zoite then gains access into an intracellular compartment surrounded by a membrane which is continuous with the host cell plasmalemma during invasion. The fate of that membrane has long been controversial since some authors have described its disintegration during the invasion, arguing that the parasitophorous vacuole appeared later around the cytoplasmic parasite. These conclusions were based on preparation artifacts due to the peculiar nature of the developing parasitophorous vacuole membrane which is poorly stabilized by the electron microscope preparation. A peculiar type of interaction occurs however between malaria sporozoites and hepatocytes, where the parasite crosses several cells by breaching their membrane using specific perforins contained by micronemes, before invading its final host cell as described below.

A very precise description of invasion has been given for *P. knowlesi*, this species being more amenable to experimental study of invasion than any other malarial parasite because of the relatively long shelf life of its merozoites. The initial step of internalization is a close contact between the apical end of the merozoite and the red blood cell plasmalemma. This latter becomes thicker on its inner side under this contact. Initiated as a segment of a sphere, this "junction" turns into a ring which moves backward on the zoite surface, whereas the host membrane area previously involved in the junction becomes the developing parasitophorous vacuole. The ring travels along the zoite to its posterior end where the junction ends up as a segment of a sphere, at which level the vacuole closes and separates from the host plasmalemma. The surface coat of the merozoite has been shown to be "shaved off" at the level of the junction as this latter went along the zoite surface.

Associated with this process is the formation of vesicles facing the zoite apex on the cytoplasmic side of the developing parasitophorous vacuole and a clear decrease in the electron density of the

rhoptry contents. The rhoptries open at the tip of the zoite, and their contents are in contact with the parasitophorous vacuole membrane. Freeze-fracture electron microscopy has shown a complete depletion of intramembranous particles of the developing parasitophorous vacuole compared to the erythrocyte plasmalemma, which indicated a very low protein content for this membrane. A second observation was that the moving junction had a peculiar freeze-fracture structure as a rhombohedral network of "particles" in the erythrocytic side, which indicated that the junction was more than a close apposition of membranes but that the internal structure of the host cell membrane was altered at this level.

From a physiological point of view, the major finding was that cytochalasin D inhibited the invasion, although the junction was initiated at the apex of the zoite and some vesicles appeared on the cytoplasmic side of the junction indicating that the actin motor was not needed for junction formation and rhoptry exocytosis, but essential for entry. Protease inhibitors were also found to block the phenomenon, which suggests that proteases may be involved in the process.

Host cell invasion by Coccidia has been studied both in vitro and in vivo. Because of the larger size of the zoites and the more complex organization of the host cells, the results obtained by electron microscopy were not as clear as for Plasmodium. Moreover, the host cells chosen for experimental studies were in some cases professional phagocytes (monocytes, macrophages), which raised additional questions concerning the active part played by zoites in entry. It is now clearly demonstrated that host cell invasion by Coccidia proceeds as described for Plasmodium, i.e., by a moving junction gliding backward on the zoite which enters a parasitophorous vacuole, the membrane of which is continuous with the plasmalemma of the host cell but depleted of intramembranous particles (Figs. 2, 3, and 4). The freeze-fracture features of the moving junction are identical to the ones found on red blood cell membranes in Plasmodium.

Cell Penetration,

Fig. 2 Invasion of a mouse reticulocyte (*R*) by a merozoite of *Plasmodium yoelii nigeriensis* (*c* merozoite cell coat, *m* moving junction, *pv* developing parasitophorous vacuole. Bar = 0.2 μ m; Courtesy of G. Prensier, original)

**Cell Penetration,**

Fig. 3 Invasion of HeLa cell (*H*) in vitro by a tachyzoite of *Toxoplasma gondii* (*R* rhoptry, *eR* empty rhoptry, *N* nucleus, *m* moving junction. Bar = 1 μ m; Ferreira and Dubremetz, original)

Abundant membrane whorls are found in the parasitophorous vacuole or in “empty rhoptries,” and vesicles named e-vacuoles are found on the cytoplasmic side of the parasitophorous vacuole, especially when invasion is blocked by cytochalasin; these vesicles contain rhoptry proteins.

Thus, the invasion process is conserved in all intracellular Apicomplexa, characterized by a moving junction and the development of the parasitophorous vacuole. The moving junction components have been recently identified in *T. gondii*: it contains proteins exocytosed from

Cell Penetration,

C

both the micronemes (AMA1) and from the anterior part of the rhoptries (rhoptry neck, RON proteins). These proteins are associated in a transmembrane complex at the junction level. This complex is believed to be moved by the parasite actomyosin motor on the parasite side. The critical part of the complex is the interaction between the microneme protein AMA1 that is transmembrane in the parasite plasmalemma and the RON2 protein that is inserted transmembrane in the host cell plasmalemma. The other RON proteins are associated to RON2 on the cytosolic side and likely involved in anchoring the complex to the host cell cytoskeleton to provide the scaffold on which the parasite glides during entry and to attach to host cell receptors or cytoskeleton. Another possibility is that the complex itself is anchored in the host cell membrane, avoiding the need for a specific receptor. A schematic view of the invasion process is shown in Fig. 5 and the molecular organization of the moving junction in Fig. 6.

The origin of the parasitophorous vacuole membrane is still controversial. The respective contributions (qualitative and quantitative) of the host cell plasma membrane and of rhoptry

products are not fully determined, although both are probably involved. Ward et al., using fluorescent lipids or electrophysiological procedures, have shown in both *P. knowlesi* and *T. gondii* that host cell membrane components (essentially lipids) contribute a major part of the early parasitophorous membrane.

The contribution of the apical secretory organelles to invasion is essential. They undergo sequential exocytosis during the process. Micronemes release proteins involved in motility recognition adhesion, at an early stage of interaction. Rhoptries then contribute components of the moving junction (RON proteins, exclusively located in the neck of the organelle) followed by proteins (and lipids) which are integrated into the parasitophorous vacuole membrane (ROP proteins, derived from the posterior part of the organelle). They contribute enzymes such as proteases or phospholipases that can modify the host cell plasmalemma and facilitate vacuole formation (e.g., the cleavage of the erythrocyte protein band 3 by a serine protease of *Plasmodium* is believed to lead to the disorganization of the spectrin network of the red blood cell as a prerequisite to red cell invasion). In addition,

Cell Penetration,

Fig. 5 Schematic drawing of the successive steps of Apicomplexa invasion. 1 A zoite glides on a host cell surface using microneme proteins exocytosed apically (curved arrow); a signal is transduced from the surface (star, arrow) to the apex. 2 The signal induces reorientation, apical binding to the host cell, rhoptry neck exocytosis, formation of the moving junction from microneme, and rhoptry neck proteins. The bulk of micronemal material is capped behind the moving junction. 3 Rhoptries are exocytosed, while the moving junction glides backward and the parasitophorous vacuole starts expanding. Rhoptry material is integrated in the vacuole membrane. 4 The vacuole keeps expanding, getting most of its lipids from the host cell plasmalemma. The junction reaches the posterior end of the parasite and eventually seals the vacuole. Dense granules are exocytosed into the vacuolar space (After Dubremetz et al. 1998, modified)

some rhoptry proteins are released in the host cell and at least two of them in *T. gondii* are targeted to the host nucleus where they modulate the host cell transcription. Dense granules are exocytosed into the vacuole after invasion, and their role is not well understood, yet they are

probably involved in rendering the vacuole contents and membrane efficient to sustain parasite metabolic needs. In *P. falciparum*, a dense granule protein (RESA) is translocated under the erythrocyte membrane and associates with spectrin.

Cell Penetration,

Fig. 6 Molecular organization of the moving junction in Apicomplexa. The myosin motor is the same as Fig. 2, but the microneme protein involved is AMA1, which interact with the RON proteins, inserted in the host cell membrane (After Besteiro et al. 2011, modified)

A peculiar process has been described for the piroplasm *Theileria*: invasion of mononuclear lymphocytes by sporozoites seems to involve a zipper mechanism in a receptor-mediated endocytosis due to specific receptors on the zoite surface. These findings are very unique among Apicomplexa and may represent an exception to the moving junction process. In addition, in this model, as in the other piroplasm *Babesia* (which invades red cells in a manner very similar to *Plasmodium*), the vacuole membrane is disintegrated after invasion, and the parasite develops in the cytoplasm of the host cell.

Cell-Autonomous Immunity

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

In general, the host defensive system is considered to be based on the peculiar and often very specialized activity of certain cell types as sole guardians. However, most types of host cells are able to defend themselves against aggressive agents of disease. This system, which is ubiquitously present, is termed as cell-autonomous immunity (CAI). Randow et al. (2013) described several abilities of any cell to defend itself against aggressions. This defense is supported or even made possible by the previous formation of several peculiarities. For example, compartmentalization of the

cell's interior promotes cellular self-defense, since penetrating parasites are enclosed in compartments (e.g., vacuoles). Abrupt breakdown of compartment borders generates disturbances in cellular homeostasis, which may block food uptake of the parasite and stimulate a potent antimicrobial defense system of the cytoplasm. Further pathways of host cell actions limit speed of the reproduction of the agent of disease inside the penetrated host cell. However, this cellular self-protection apparently acts only by slowing down the reproduction rate of an aggressor, so that the specialized defense/killer cells get more time to become developed and transported to the side of an aggression.

Cement Glands

Cement glands are significant accessory organs (1–8 in number) in ► *Acanthocephala*. In addition, *Eoacanthocephalans* have a separate cement reservoir. The vasa efferentia fuse to form a vas deferens, which fuses with one or several ducts of the cement gland(s) to form a genital canal. The cement locks the female vagina after copulation until the first embryonated eggs are released, and forms typical copulatory caps on the posterior tips of inseminated females (*Acanthocephala*/Reproductive Organs).

Centriole

This cell organelle consists of a hollow tube of a length of 0.3–0.6 µm and a diameter of about 0.2 µm. It is formed by nine concentrically arranged triplets of short microtubules (also seen in the basal body of ► *cilia*). A pair of these centrioles (being arranged perpendicularly to each other) form the so-called centrosome, which is thought to function as a microtubuli organizing center (► *MTOC*) of the spindle apparatus during

► *nuclear divisions*. Centrioles thus reduplicate before cell/nuclear divisions. In ► *Coccidia* so-called centriole-like structures consisting of nine single outer microtubules and a central one with apparently similar functions occur.

Centrocestus armatus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species belongs to the group of heterophyid trematodes and is found in Japan, Taiwan, China, Korea, in a wide range of wild and domestic animals, but in considerable numbers also in humans. First intermediate hosts are fresh water snails of the genus *Semisulcospira*, second intermediate hosts (with metacercariae) are fresh water fish, where the gills are entered by the cercariae within 1–5 min. Final hosts are fish eating mammals.

flies of the Caribbean islands; Trivial: no-see-ums

General Information

This family of ► [Diptera](#) comprises four genera: *Culicoides*, *Leptoconops*, *Lasiohelea*, and *Austroconops* (Figs. 1–5). *Culicoides* is the most widespread and abundant with 800 species

Ceratopogonidae, Fig. 1 LM of a female *Culicoides obsoletus*

(Table 1). There are fewer species (120) of *Leptoconops*, but they are widely distributed, and their bite is even more painful than that of *Culicoides*. The genus *Lasiohelea* is as widely distributed as *Leptoconops* with relatively few species (150). Only one species is known of *Austroconops* (*A. macmillanii*) in Australia.

The size of the bloodsucking females of all species/genera is very small; several do not reach a length of even 1 mm. Their behavior, their sucking activities, and their habitats = brood places vary considerably – even among the species of a genus.

Mating

In general mating occurs prior to blood meal, which is in general necessary to lay eggs. However, there are species which are apparently parthenogenetic (e.g., *C. circumscriptus*). Males of most species form swarms.

Blood Meals

Most species have preferences for hosts; e.g., humans are heavily attacked by *C. impunctatus*, while others prefer birds, cattle, deer, etc. However, in case of hunger, they may switch to other hosts. There are also preferences with respect to the biting spot (leg, arm-shaded underside of cattle, etc.).

					Products	Application	Compounds
<i>Culicoides</i> spp. (biting midges, no-see-ums or punkies)	Ruminants, Horse	Bluetongue virus (Cattle, Sheep), African Horse sickness virus, <i>Onchocerca cervicalis</i> (Horse)	Edema, allergic reactions. Skin nodules	Worldwide	Butox TM , Bayofly TM	Spray	Pyrethroids
<i>Forcipomyia taiwana</i>	Humans	Japanese-B-encephalitis virus	Encephalitis	Asia	Repellants	Spray	Deet, Picaridin

Eggs

The numbers of eggs produced and laid in batches of less than 100 depends on the amount of blood taken up.

Breeding Sites

Their eggs are – depending on the species – deposited at definite places. For example, *C. imicola* and *C. dewulfi* breed in dung of cattle and horses, *C. pulicaris* is found in swamps/soil, and *C. maritimus* uses salt marsh, while the European *C. obsoletus* group breeds hidden in straw of tree leafs or *C. fagineus* are restricted to tree holes. *Leptoconops bequaerti* also breeds in pure sand hidden in holes during tides. The larvae of all three genera differ in shape (Fig. 3).

Length of Life Cycle

This depends on the temperatures. Many temperate species have either one or two generations per year. Others – as *C. obsoletus* in Europe – may only occur from March until the end of October. In general, the temperate species overwinter as larva 4 and pupate in the following year. However, in warm countries *C. pulicaris* and *C. obsoletus* in South Italy or in the tropics may occur throughout the year.

In general, adult females of *Culicoides* do not live longer than 3–4 weeks. However,

C. obsoletus specimens were found to survive often up to 3.5 months.

Daily Activity

Most species of *Leptoconops* and a few of *Culicoides* are diurnal, while most *Culicoides* are crepuscular species showing great activity at dawn and dusk (e.g., *C. imicola*, *C. obsoletus*). However, some (e.g., *C. grahamii*) are also active throughout the night, others only in the night. Since these insects are all very small, they can be driven away easily even by winds with a maximum speed of 5–8 km/h. Thus potentially infected midges can spread over long distances within a single night.

Vectors

Ceratopogonids are known vectors of viruses and bacteria such as ► *Francisella tularensis*. Recently outbreaks of ► *blue tongue virus* disease occurred in Europe involving serotypes 1, 2, 4, 9, and 16 and most recently in Germany (2006) serotype 8. The viruses may survive for more than 150 days inside the defense cells of ruminants. Especially the so-called T-cells may contain these viruses for long and initiate new transmission to the new generation.

Ceratopogonidosis

Disease due to bite of ► *midges* (Table 1).

Cercopithifilaria

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This genus belongs to the nematode family Onchocercinae (Filariae). Its species (e.g., *C. grassi* and *C. baina* of dogs and *C. johnstoni* of rats and several other mammals) are common and reach prevalence rates of up to 10 %. The microfilariae are found mainly in lymph vessels of the skin, while the adults are located in the sub-cutaneous tissues. However, the microfilariae are

also found in the eyes, where they may induce ocular lesions. Vectors are ixodid ticks in –South Europe, Africa, and South America (in South Europe *Rhipicephalus sanguineus* (= Brown dog tick) is the main vector.

Cercopithifilaria Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *kerkos* = tail; Latin: *filum* = filament.

This genus of filarial worms comprises three described species: *C. baina*, *C. grassi*, and *C. sp.*, which parasitize dogs, where they live as adults and microfilariae inside the cutaneous tissues (trunk, forelimb, posterior limb, etc.). Males of *C. baina* reach 9–12 mm in length, while females measure 14–19 mm. Their microfilariae have a length of 185–197 µm, while those of the unnamed species reach 270–300 µm. Those of *C. grassi* are much longer and reach a maximum length of 670 µm, while their adults range in the size of the two other species. The transmission of the microfilariae from dog to dog occurs by blood sucking ticks (*Rhipicephalus sanguineus*, *Ixodes* species, *Hyalomma truncatum*). There are further *Cercopithifilaria* species (e.g., *C. eberhardi*, *C. narokensis*, *C. kenyensis*) which all parasitize baboons besides nine others based on a phylogenetic tree.

Cerebrospinal Fluid: CSF

Puncture of CSF and its microscopical investigation is an effective way to diagnose stained or living *Naegleria* amoebae in cases of PAM (Primary amoebic meningitis).

Cestodaria

Classification

Subclass of ► [Cestodes](#).

General Information

Cestodaria are monozoic hermaphroditic worms which are not subdivided and include only a single set of male and female reproductive organs (► [Eucestoda](#), Fig. 2). Their holdfast organs (if present at all) are not very well developed (► [Amphilina foliacea](#), Fig. 1), but allow them to inhabit the intestine or the coelom of their hosts. In ontogenesis a 10-hooked ► [lycophora](#) larva is involved. With respect to body organization and life cycles two orders can be distinguished: Amphilinidea and Gyrocotyliidea (► [Amphilina foliacea](#), Fig. 1, ► [Gyrocotyle](#), Fig. 1). Members of the Amphilinidea are parasitic in the coelom of sturgeons, other primitive fish, and tortoises, usually reaching a size of 2–8 cm (but up to 38 cm in species of *Gigantolina*). These ribbon-like

monozoic and monoecious worms have their genital pores (vagina, male ► [cirrus](#)) at the posterior end (► [Amphilina foliacea](#), Fig. 1), but in the female the uterus opens at the anterior end. The parent worms bore through the body wall of the fish host to lay their eggs. Inside excreted eggs a larva (lycophora) is formed, the surface of which may be ciliated (► [Amphilina foliacea](#) of the European sturgeon) or not (*Gephyrolina paragonopora* of siluroid fish); the larva can reach a length of about 100 µm and has 10 hooks at the posterior end. In *A. foliacea* the egg must be swallowed by an intermediate host (an amphipod crustacean), inside which the lycophora hatches, sheds its ciliated epidermis, and finally enters the hemocoel. Inside the body cavity of the intermediate host the lycophora elongates and attains the appearance of a ► [proceroid](#) and a ► [plerocercoid](#). When the amphipod host is ingested by a sturgeon, the plerocercoid burrows through the intestinal wall of the final host, and enters the body cavity, where it attains sexual maturity.

Members of the order Gyrocotylidea primarily inhabit the intestines of marine chimaerid fish, being attached to the wall by their posterior ► [rosette](#). They reach a length of up to 25 cm and have all three genital pores at their apical pole (► [Gyrocotyle](#), Fig. 1). Inside the fecally passed, operculated eggs, the 10-hooked lycophora larva develops within 30 days. In ► [Gyrocotyle urna](#) the lycophora is ciliated (but not in other species) and leaves the egg shell. An intermediate host is not yet known, and apparently not necessary, since 3–5-mm-long proceroid-like larvae with a well-formed typical terminal rosette have been found in several host fish.

Cestode Infections

General Information

► [Cestodes](#) live as intestinal parasites firmly attached to the mucosa of the gut in their definitive hosts where they can live for years (e.g., ► [Taeniasis](#), [Animals](#), ► [Taeniasis](#), [Man](#)). Gravid

proglottids or eggs are released in the feces and ingestion of eggs by susceptible intermediate hosts results in the release of larvae, also called oncospheres within the gastrointestinal tract. The oncospheres penetrate the intestinal mucosa and migrate into tissues of the host where they can develop into mature metacestodes (e.g., ► [Cysticercosis](#), ► [Echinococcosis](#)). Important cestode infections are listed in ► [Platyhelminthic Infections](#), [Man](#), [Pathology](#).

Immune Responses

While relatively little is known on immunity against the adult ► [tapeworms](#) in the gut, mechanisms of host–parasite interactions and the immune response have been extensively studied for the tissue stages. In larval cestode infections the intermediate mammalian host harboring egg-derived metacestodes in the tissues becomes completely immune to reinfection with eggs. In contrast, autoinfections with eggs occur in the case of ► [Taenia solium](#) when the host is initially infected with metacestode-derived adult tapeworms in the gut lumen.

Greek: *kestos* = band, belt.

Synonyms

Tapeworms

Classification

Class of ► [Platyhelminthes](#).

General Information

All members of the class Cestoidea live as parasites, are extremely dorsoventrally flattened, may reach a length of several meters in some species, and thus are called tapeworms. In general, the adults inhabit the intestines of their hosts, being anchored to the intestinal wall by means of type-specific holdfast organs (Fig. 1). Their principal body organization corresponds to that of ► [trematodes](#) with the exception of the lack of an intestine; thus all nutrients have to be taken up through the syncytial ► [tegument](#) (Figs. 1, 3, 4, and 5). The ontogenesis of the cestoda proceeds in most species as ► [metamorphosis](#) employing different larval stages (Fig. 2). In relatively rare cases (e.g., ► [Echinococcus](#) spp.; Fig. 2), an alternation of different generations is involved in the life cycle;

however, all tapeworms need an alternation of hosts (see ► [Eucestoda](#), Table 1). The classification of the class Cestoda is far from being solved (cf. ► [Classification](#)); however, most systems accept two subclasses which are differentiated with respect to the number of larval hooks. The medically unimportant ► [Cestodaria](#) form ten larval hooks and are thus described as ► [decacanth](#), whereas the larvae of the ► [Eucestoda](#) have only six hooks (► [Hexacanth](#)).

System

Important Species

► [Eucestoda](#), Table 1.

Cestodes, Fig. 1 Diagrammatic representation of scolices in different orders of tapeworms

Integument

In cestodes a gut is lacking. Therefore, nutritional uptake has to be mediated completely by the tegument surface. Moreover, the tegument has to resist the attack of digestive enzymes and protect against the immune responses of the host. Tapeworms may be affected by the immune response of their host. Initially, destrobilized worms are not permanently damaged but will recover if they are transplanted into nonimmune hosts. It has been assumed that inactivation of proteases and lipase occurs on the surface of the tegument.

The external tegumentary membrane covering the ► **microtriches** has a ► **surface coat** which is a highly dynamic structure. Using [^3H]-

galactose as a label it was shown that the surface coat had a turnover rate of about 6–8 h in

► *Hymenolepis diminuta*. Autoradiographic investigations revealed that the constituents of the surface coat are synthesized by the endoplasmic reticulum and Golgi complexes of the perikarya and that they are transported to the apical part of the tegument. Histochemical methods demonstrated the presence of carbohydrates and negatively charged compounds in the surface coat. Biochemical investigations revealed a variety of glycoconjugates in tegumental extracts of *Hymenolepis diminuta* and ► *Spirometra mansonoides* which are assumed to take part in the replenishment of the surface coat.

Cestodes, Fig. 2 (a–j) Different larval stages of Eucestoda. *BO* bothria (sucking grooves), *BR* brood capsules, *CI* ▶ cilia, *G* germinative layer (consisting of undifferentiated cells inside TG), *HK* hooks of

Cestodes, Fig. 3 (a, b)

Microtriches at the surface of the tapeworm

► *Hymenolepis microstoma* after incubation of intact worms with lectin-gold conjugates. Bars 0.5 µm. (a) The surface coat of the electron-dense spines of the microtriches is densely covered with SBA gold. Only a few granules are present at the proximal part of the microtriches. This pattern of lectin binding was also found with other lectins and in other species, notably *H. nana*. (b) In the anterior parts of the ► strobila where the proglottids grow, a filamentous layer can be observed on top of the microtriches which binds SBA gold strongly

**Cestodes,**

Fig. 4 *Hymenolepis diminuta* after incubation of the intact worm with SBA gold. Only the anterior parts are covered with SBA gold. Bar 0.5 mm

Extracted surface material and in vivo products of larvae of *Taenia taeniaeformis* have been shown to contain a sulfated glycoconjugate. Its oligosaccharide chains contain glucosamine, galactose, and glucose at proportions of 4:4:1. This glycoconjugate is secreted and able to activate the complement cascade in vitro. It is

assumed that it lowers the complement level in the surroundings of the parasite and thus prevents activation of complement at the external tegumentary membrane.

Gold-labeled lectins have been used to localize, by light and electron microscope, terminal sugar residues of the ► surface coat of

Cestodes,

Fig. 5 Diagrammatic representation of five tapeworms. *LP* empty proglottids, *P* proglottids, *S* scolex, *U* uterus with eggs

Hymenolepis nana, ► *H. microstoma*, and *H. diminuta* (Figs. 3 and 4). Light microscopic sections of *Hymenolepis microstoma* were labeled with lectin-gold conjugates. It was shown that the tegument binds wheatgerm agglutinin (WGA) and soybean agglutinin (SBA) strongly but peanut agglutinin (PNA) and

Concanavalin A less intensely. Electron microscopic investigations of *H. microstoma* and *H. nana* demonstrated that WGA, succinylated WGA, SBA, *Abrus precatorius* agglutinin (APA), PNA, and, to a lesser extent Concanavalin A were preferentially bound to the spines of the microtriches, which indicated that the surface of

these species had exposed *N*-acetylglucosamine, galactose, and perhaps glucose and/or mannose residues. *Ulex europaeus* (UEA) 1 and *Dolichos biflorus* agglutinin (DBA) were not adsorbed, which means that terminal L-fucose and *N*-acetylgalactosamine residues seem to be absent. Specificity was controlled by competition with the respective sugars or sugar derivatives. Lectin-gold particles adsorbed mainly to the surface of the electron-dense spines. Only a few particles were found at the proximal part of the microtriches. This binding pattern does not appear to be the result of ► [capping](#), since similar results were obtained with worms which had been fixed with glutaraldehyde prior to incubation. The carbohydrate constituents of the surface coat seem to be of parasite origin and do not represent adherent intestinal mucus from the host. The latter readily adsorbed UEA 1- and DBA-gold particles which were not bound by the tapeworm surface.

H. nana inhabits the posterior part of the ileum of the mouse, whereas *H. microstoma* is attached in the bile duct and extends into the intestine. Nevertheless, no differences were observed in the lectin-binding pattern of both species. However, the rat tapeworm, *H. diminuta*, differs markedly from these two species. It is expelled by normal mice 8–13 days after infection by unknown mechanisms, but it is able to develop in immunodepressed mice. In this species lectins specific for *N*-acetylglucosamine and galactose are adsorbed only at the scolex and adjacent parts but not on the strobila. The same lectins are adsorbed by the whole tegumental surface of *H. nana* and *H. microstoma*. The immune system of the mouse above all destroys the strobila of *H. diminuta* and leaves the scolex region intact. Destrobilated worms may survive for at least a few days. Therefore, it is tempting to assume that the glycoconjugates which are present in this region might be responsible for the resistance to immune reactions of the host. A striking difference in the polysaccharide content of two species appears to be in accordance with this assumption. A polysaccharide which is present in larger amounts in a resistant species, *H. microstoma*, appears only in traces in *H. diminuta* which is eliminated by the mouse. No protein or uronic

acids were demonstrated. Negative charges are due to acetyl groups.

Befus was able to demonstrate the C3 component of complement on the surface of *H. diminuta* in the mouse but found it inconsistently and only in small amounts in *H. microstoma*. Contrary to these results, other groups found that only small amounts of C3 were deposited on the surface of *H. diminuta* in vivo, whereas in vitro C3 was bound in large amounts. Mouse complement proved unable to lyse the tegumental membrane of the rat tapeworm. However, that and human sera are able to destroy the surface of the tegument of *H. diminuta* in a few minutes. Therefore, the complement system of the mouse cannot be responsible for the elimination of *H. diminuta* from its gut, and it appears more likely that this is effected by cellular mechanisms.

Diseases

► [Taeniasis, Animals](#), ► [Taeniasis, Man](#), ► [Cysticercosis](#), ► [Echinococcosis](#), ► [Cestode Infections](#).

Cestodocidal Drugs

See Tables [1](#) and [2](#)

Economic Importance and Epizootiology

► [Tapeworms](#), which belong to the phylum Platyhelminthes, are hermaphroditic, endoparasitic, elongate, flatworms without a body cavity or alimentary tract, a few millimeters to several meters in length. As a rule economic loss, resulting from cestode infections is less severe than that due to trematode or nematode infections. Adult stages of tapeworms living in the alimentary tract of the final host are remarkably benign although adults may be up to 8 or 15 m in length (e.g., *Taenia saginata*, *Diphyllobothrium latum*). The scolex of the strobilate stage in eucestodes is provided with holdfast organs

Cestodocidal Drugs, Table 1 Drugs used against cestode infections of domestic animals (Raether and Harder)

Chemical group nonproprietary name of active substance (single oral dose, mg/kg body weight = b.w.), other information	*Drug product dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	Characteristics: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and contraindications
Alkaloids	Drug products are now disapproved in the USA, Australia, European countries, elsewhere; bitter-tasting powder; addition of sucrose (15 %) is recommended; may be given as 1.5 % solution	It may still serve as a diagnostic drug for cestode infections in dogs (<i>Echinococcus</i> spp., <i>Taenia</i> spp.); it has strong parasymphatomimetic actions causing increased peristalsis so that the paralyzed worm loses its attachment to intestinal mucosa and is expelled live and intact; its action on <i>E. granulosus</i> is variable but it shows good efficacy against <i>Taenia ovis</i> , <i>T. pisiformis</i> (other <i>Taenia</i> spp.), and <i>Dipylidium caninum</i> if the purging effect occurs sufficiently (onset of catharsis usually occurs 15 min after administration but some dogs may not defecate); the drug should not be used in cats, pregnant bitches, or in pups less than 6 months of age; its safety margin is narrow; atropine sulfate (0.04 mg/kg) may be used as antidote (does not interfere with the cestocidal action of arecoline)
Arecoline acetarsol (5) (tasteless, odorless, white powder; was formulated into scored tablets)	Drug products (e.g., *Nemural, others) are now disapproved in the USA, Australia, European countries, elsewhere	Its action is similar to that of the arecoline hydrobromide; following ingestion of tablet the complex hydrolyzes in stomach releasing active arecoline which causes increased peristalsis, detachment of paralyzed worm and its expulsion (onset of catharsis usually occurred 30 min after administration); pups less than 3 months of age and cats less than 6 months of age should not be treated; arecoline acetarsol was not well tolerated (frequently vomiting, rarely salivation, restlessness, labored breathing, ataxia)
Inorganic compounds		
Tin compounds (mixture of metallic tin, tin oxide, or di-butyl-tin dilaureate chloride) were used several decades ago as anticestodals for humans; it has been assumed that anticestodal action of tin compounds may be due to coating tapeworm's integument (cuticle) with a thin layer of tin particles, which renders tapeworm strobila susceptible to digestion; tin preparations exhibited a moderate cestocidal activity (70–90 %) against <i>Taenia</i> spp. in humans (dose regimen: once a day over a period of several days); di- <i>n</i> -butyl tin dilaureate (100–125 mg/kg b.w., given in-feed) has been used (may still used occasionally elsewhere) in poultry flocks and in cage birds; today the cheap compound has been replaced by niclosamide and other anticestodals; di- <i>n</i> -butyl tin laureate was highly effective against <i>Railiellina</i> spp. but not so against <i>Choanotaenia</i> spp. and <i>Davainea proglottina</i> (variable effects); it was well tolerated at recommended dose but could cause a temporary drop in egg production		
Lead arsenate was first used as an insecticidal drug, and has been found by chance to be effective also against tapeworms of sheep; for a long time it had been used worldwide as an inexpensive anticestodal drug with almost 100 % effectiveness against <i>Moniezia</i> infections in lambs, kids, and calves (single dose in capsules: 0.5 mg/kg b.w.: calves, kids <3 months of age; 1 g/head: lambs >2 months age, calves >3 months age); its safety margin was low, and 2 g/head daily for 2 days (or 1 g daily for 6 days) caused mortality in sheep (profuse diarrhea, oliguria, extreme weakness, enhanced permeability of capillary, and resulting shock); the drug was contraindicated in poultry		

(continued)

Cestodocidal Drugs, Table 1 (continued)

Phenol derivatives	*Vermiplex, *Tri-plex, (Schering-Plough), *Anaplex Caps (Boehringer Ingelheim) *Difolin Capsules (Fort Dodge AH), all capsules, many other sponsors (all USA)	
Dichlorophene/toluene (single dose per os: 220/264 mg/kg b.w. dog, cat, (divided dose per os: 100/120 mg/5 lb b.w. = 20/24 mg/lb daily for 6 days)	Several drug products containing <i>dichlorophene/toluene</i> may still have rather wide use in small animal practice, approved indications (dogs/cats): for removal of ascarids (<i>Toxocara canis</i> , <i>Toxascaris leonina</i>) and hookworms (<i>Ancylostoma caninum</i> , <i>Uncinaria stenocephala</i>) and as an aid in removing tapeworms (<i>Taenia pisiformis</i> , <i>Dipylidium caninum</i> , and <i>Echinococcus granulosus</i>); limitations (dogs/cats): withhold solid foods and milk for at least 12 h prior to medication and for 4 h afterward, repeat treatment in 2–4 weeks in animals subject to reinfection; dichlorophene products (as sole active ingredient) are no longer available; they gave an alternative to arecoline that was unpleasant in use; dichlorophene (introduced in 1946) is chemically similar to niclosamide (both are phenol derivatives) it has bactericidal, fungicidal, and anticestodal activity; its anticestocidal spectrum includes variable efficacy (only destrobilating action) against <i>Taenia</i> spp. (± 72 % efficacy) and <i>Dipylidium caninum</i> (± 85 % efficacy) in dogs and cats; its efficacy against <i>E. granulosus</i> is variable; it has limited efficacy against <i>Moniezia</i> spp. and <i>Thysanosoma</i> in sheep (therapeutic dose sheep: 200 mg/kg b.w.); dichlorophene shows low toxicity (LD50 in rats 2.6 g/kg); this is due to poor absorption of the drug from the alimentary tract; however, drug may be toxic in cats; adverse effects are vomiting and colic diarrhea;	
Toluene (a hydrocarbon obtained from coal tars or methylbenzene) is only available in combination with <i>dichlorophene</i> ; it has efficacy against GI nematodes as ascarids (~ 98 % efficacy), hookworms (~ 95 % efficacy) and whipworms (~ 40 % efficacy: not approved indication) of dogs and cats; usually it is fairly well tolerated in therapeutic doses; at 5 times the therapeutic dose; adverse effects may occur in older animals as vomiting, muscular tremor, and ataxia	in dogs, cats (little efficacy against <i>D. caninum</i>), poultry (<i>Raillietina</i> spp., <i>Choanotaenia</i> in chickens, geese, quail), and <i>Moniezia</i> , <i>Thysanosoma</i> , and <i>Paramphistomum</i> (~ 85 % efficacy) in ruminants; it is well tolerated in these animals but may stimulate purgation in dogs and cats; in contrast to bithionol, <i>bithionol sulfoxide</i> has the advantage of a lower therapeutic dose (60 mg/kg) against adult cestodes (adults are expelled intact), its antirematodal efficacy against liver flukes in sheep and cattle is superior to that of the parent compound	
Bithionol (~ 200 per os cats, dogs, sheep, goats, quail) (~ 200 , 2 times in 4-day intervals, chicken) (~ 600 geese) bithionol sulfoxide (sulfene, syn. sulphene)	Preparations of the drug and its derivatives may still be used outside North America, Europe, Australia, elsewhere; earlier known as *Bithin, others; poultry: in-feed, other animals capsules, tablets, or boluses	

Hexyloxy-naphthamidines Bunamidine hydrochloride (BUH) (25–50 dog, cat) dog and cat, no use class stated or implied	*Scolaban 400 (Schering-Plough AH, USA), coated tablet containing 400 mg BUH do not crush tablet (cf. limitations ☐)	Has been used worldwide after its introduction in 1965 against tapeworm infections of dogs and cats; it quickly replaced arecoline and dichlorophene for routine treatment of cestode infections in cats and dogs; *Scolaban is approved in the USA (elsewhere ?); BUH is active against <i>Taenia</i> spp., <i>Dipylidium caninum</i> (effect varies), <i>Spirrometra</i> spp., and <i>Echinococcus granulosus</i> in cats and dogs; for some years it was the drug of choice against <i>E. granulosus</i> (50 mg/kg, repeated after 48 h empty stomach); however, its effect on <i>Echinococcus</i> is not 100 % and allows some worms to survive; about 10 years after its introduction, it was replaced in hydatid control schemes by <i>praziquantel</i>; BUH exhibits activity against <i>Moniezia expansa</i> in sheep, and shows variable efficacy against ascarids in dogs and cats (not approved indications); approved indications: is intended for oral administration to dogs for the treatment of <i>D. caninum</i>, <i>T. pisiformis</i>, and <i>E. granulosus</i>, and to cats for the treatment of <i>D. caninum</i> and <i>T. taeniaeformis</i>; limitations: oral tablet should not be crushed, mixed with food, or dissolved in liquid (dogs, cats), repeat treatments should not be given to dogs and cat within 14 days, BUH should not be given to male dogs within 28 days prior to their use for breeding, do not administer to dogs and cats having known heart conditions; for use only by or on the order of a licensed veterinarian; <i>mode of action</i>: BUH acts as taeniocide; it affects tegument of <i>Hymenolepis nana</i> causing disruption of the outer layer, which leads to decrease in the rate of glucose uptake and an increase in the rate of glucose efflux; damaged outer layer allows digestion of the worm in the host; tolerability and adverse effects: it is relatively well tolerated at recommended dose; side effects are transient diarrhea and occasional vomiting: crushed tablet may cause irritation of oral and stomach mucosa, and thus enhanced drug levels in blood plasma producing unexpected toxic effects; detoxification of drug likely occurs in the liver; cases of sudden death have occasionally been seen in dogs without evidence of hepatic dysfunction; liver disorders may lead to higher levels of BUH in the circulation; in excited dogs, high levels of epinephrine may then cause ventricular fibrillation in heart sensitized by BUH to endogenous catecholamines; excitement and exertion should be avoided after treatment; reduced spermatogenesis was found in dogs but not in cats; the drug is well tolerated in bitches (all stages of pregnancy); bunamidine hydroxynaphthoate (25–50 mg/kg b.w. per os: *Buban) has been used in the UK as a drench for control of tapeworm infections in sheep and goats; the salt (insoluble in water and less irritant to mucous membranes than the hydrochloride) exhibits marked efficacy against <i>Moniezia expansa</i> and <i>M. benedeni</i> in naturally infected sheep and goats; metaphylactic treatment (single dose) was during spring/summer and in autumn when reinfection occurred; the drug was tolerated in sheep and goats at twice the recommended dose; given in feed, it showed variable activity against <i>Taenia</i> spp. in dogs; it was tested in <i>poultry</i> with natural infection of <i>Raillietina</i> spp. and <i>Amoebotaenia sphenoides</i> and was found to be highly active at 400 mg base/kg per os
---	--	---

(continued)

Cestodocidal Drugs, Table 1 (continued)

Salicylanilides *1 niclosamide (mono-hydrate) (NIC) <i>Australian market</i>, elsewhere: drug combinations only, doses for oral tablets:	1* Mansonil drench (Bayer Australia) for control of tapeworms and immature stomach fluke of sheep and lambs, powder/liquid	Announced in 1958 and introduced into the market in 1960; since then it has been used worldwide against tapeworm infections of animals and humans, good
NIC/levamisole HCl (LEV): e.g., *Ambex (Bo mac): (100/4.25 LEV base dog cats) NIC/pyrantel pamoate (PYR): e.g., *Troy All Wormer (Troy Labs.): (100/14.4 dog) (60/23 cat, kittens) approved indications: for the control of roundworms, hookworms and tapeworms (except <i>E. granulosus</i>) in dogs and cats (do not overdose)	(790 g/kg NIC: 5 mL/10 kg b.w.) NIC is combined with nematocidal drugs (drug form: tablets, paste) to have an advantage in that both nematodes and cestodes can be treated in dogs and cats (for further information on dosages, drug products, sponsors, suppliers, companies, and characteristics of these drug combinations cf. ► Nematocidal Drugs, Animals/Table 5)	Tolerability, a wide safety margin, and excellent efficacy against <i>Taenia</i> spp. infections of mammals have accounted for its widespread use as a taniacide in human and veterinary medicine; now, it has largely been replaced in all fields by praziquantel that shows superior cestocidal action compared to niclosamide; NIC may be also used as a molluscicide for the control of freshwater snails, which serve as an intermediate host for trematodes e.g., <i>Schistosoma</i> spp. (cf. ► Trematodocidal Drugs); NIC is highly active against tapeworm infections in dogs, cats, ruminants, and poultry; it shows marked activity against <i>Taenia</i> spp. but erratic activity against <i>Dipylidium caninum</i>, <i>Mesocostoides corti</i>, and poor efficacy against <i>M. lineatus</i> and <i>Echinococcus granulosus</i> in dogs; immature stages of <i>E. granulosus</i> may be susceptible to 50 mg/kg b.w. given on two consecutive days; the drug exhibits excellent activity against adult stages of <i>Moniezia</i> spp., <i>Thysanosoma actinoides</i> (fringed tapeworm), <i>Thysaniezia giardi</i> and <i>Avitellina</i> spp. in ruminants; it was widely used against infections of anoplocephalids in horses (80–100 mg/kg b.w.) and may still be used for control of <i>Hymenolepis</i> spp. and <i>Railietina</i> spp. infections of birds (100 mg/kg); it also affects cestode and skin fluke (<i>Gyrodactylus</i>, 0.1 mg/L, water-bath for 60 min) infections of fish (<i>Bothriocephalus</i>: 40 mg/kg daily for 3 days, or 0.5 % medicated feed); mode of action: niclosamide inhibits the formation of mitochondrial energy, i.e., oxidative phosphorylation; in susceptible adult stages uptake of oxygen and glucose is blocked; its major action takes place in the scolex and proximal segments; drug produces spastic and/or paralytic action in vitro on various preparations of helminths (e.g., <i>D. caninum</i>, <i>F. hepatica</i>); tolerability: it is a very safe drug (poor gastrointestinal absorption) also during pregnancy and lactation in cattle and sheep; dogs and cats appear to be more sensitive to the drug although twice the normal dose is well tolerated; derivatives have been prepared mainly by Russians as various salts and esters; among them the piperazine salt <i>phenolsulfophthalein</i> (PSP) is approx. two times more effective against <i>Moniezia expansa</i> in lambs than the parent drug; in countries of the earlier USSR it may still be used in animals and humans; limitations: it should not be used in combination with <i>organophosphate</i> compounds (enhanced toxic effects)
Resorantel (65 mg/kg b.w., per os: drench), chemically a 4'-bromo-γ-resorcyranilide (*Terenol discontinued in member states of European Union, may still commercially available in parts of Europe and Russia) was highly effective (95–100 %) against various cestodes such as <i>Moniezia</i> spp. infections in sheep and cattle, <i>Thysaniezia giardi</i> and <i>Avitellina</i> spp. infections in sheep; the drug showed also good efficacy (90 %) against mature and immature stages of <i>Paramphistomum cervi</i> (rumen fluke) in cattle, sheep, and		

goats; there was slight, transient diarrhea following treatment at recommended dose; the drug was excreted quite rapidly (total residues 3 days after treatment was about 0.1 % of total) Nitroscanate, chemically a substituted diphenylether, introduced for use in dogs in 1973 (50 mg/kg b.w., per os tablets: micronized particles, earlier *Lopato1 (Novartis), others, no longer available in Germany but available in Switzerland, not approved in the USA, Australia, elsewhere, for other information cf. ► Nematocidal Drugs, Animals/Table 5); it is a broad-spectrum compound with activity against roundworms (<i>Toxocara canis</i>, <i>Toxascaris leonina</i>), hookworms (<i>Ancylostoma caninum</i>, <i>Uncinaria stenocephala</i>), and tapeworms (<i>Taenia</i> spp., and <i>Dipylidium caninum</i>) of dogs; its action on whipworms is poor and that on <i>E. granulosus</i> is somewhat erratic at recommended dose; even at repeated doses of 200 mg/kg, total elimination of adult <i>E. granulosus</i> is not always achieved; therefore it is not recommended against these worms; the drug is poorly absorbed from gastrointestinal tract but irritates gut's mucosa resulting in relatively high incidence of vomiting (10–20 % of treated dogs) within 3–5 h after treatment; fasting, 12–24 h prior to treatment followed by a small quantity of food thereafter will markedly reduce vomiting; nitroscanate should not be used in cats, as it frequently provokes adverse side effects at therapeutic dose; mode of action in cestodes appears to be an uncoupler of oxidative phosphorylation (the drug inhibits ATP synthesis in <i>Fasciola hepatica</i>)		
Pyrazinoisoquinolines	1*Droneit (Bayer, USA, Australia, Germany, elsewhere) tablets, solution for injection for cat and dogs; spot-on for cats, other drug products in Germany, Australia;	PZQ was introduced in 1975 for treatment of cestode infections in cats, and dogs; it is also the drug of choice for treatment of intestinal tapeworm infections of man (cf. Table 2) and human schistosomiasis (cf. ► Trematocidal Drugs/Table 2); <i>Taenia</i> spp. and <i>Diphyllobothrium</i> spp. infections in <i>humans</i> may be eliminated by oral doses of 10 and 25 mg/kg, respectively; PZQ has no action on nematodes; the drug is extremely active after a single oral, subcutaneous (being less effective), or intramuscular dose (route may depend on cestode species) against juvenile and adult tapeworms of carnivores such as <i>Taenia</i> spp., <i>Dipylidium caninum</i>, <i>Diphyllobothrium latum</i>, <i>Spirometra</i> spp. (<i>S. mansonioides</i>, <i>S. erinacei</i>), <i>Mesocostoides corti</i>, <i>Echinococcus granulosus</i>, and <i>E. multilocularis</i> (i.m. injection is recommended in case of <i>Echinococcus</i> infection); for removal of adult <i>Spirometra</i> spp., <i>D. latum</i> it is necessary to enhance the PZQ dose (25 mg/kg b.w. once a day for 2 days); the drug exhibits also high efficacy against tapeworms of ruminants, e.g., <i>Moniezia</i>, or “bile duct” cestodes as <i>Thysanosoma actinoides</i> and <i>Stilexia hepatica</i> or <i>Avitellina</i> in sheep, goats (10–15 mg/kg b.w., single dose not approved), or cestodes of birds, snakes, and fish; it is also active against certain flukes of sheep (e.g., <i>Eurytrema pancreaticum</i>) or intestinal fluke <i>Fasciolopsis buski</i> of swine (50–70 mg/kg and 30 mg/kg b.w., respectively, single dose not approved) or skin fluke of fish (<i>Gyrodactylus aculeatus</i>: 10 mg/L water-bath for 2–3 h); PZQ has some <i>ovicidal</i> action on <i>E. granulosus</i> eggs released from the proglottid; however, eggs located in the proglottids are not affected by the drug (this limits epidemiological value of its ovicidal effect); action on tissue stages (metacestodes in liver, lungs, brain, elsewhere) residing in various intermediate hosts: activity of PZQ against larval forms (hydatid cysts) of the dog tapeworm <i>E. granulosus</i> is variable and benzimidazole carbamates (<i>mebendazole</i>, <i>albendazole</i>) prove to be more active against hydatids in sheep or man following long-term administration of these drugs; in cattle and sheep its action on larval stages (<i>Cysticercus</i>) of most <i>Taenia</i> spp. is about 100 %; this is also true for the larval stage of the human tapeworm <i>T. saginata</i> in cattle; pharmacokinetics: there is almost complete absorption from the alimentary tract following oral administration; PZQ is conveyed throughout the body and reaches high plasma levels in tissues of almost all organs; this puts it in a position to be in close contact
Praziquantel (PZQ) *1 (5–10 per os, s.c., i.m. dog, cat, dose may vary depending on b.w. and age of animal) (20–25 wild carnivores per os, s.c., i.m.: <i>Joyeuxiella pascualei</i> or <i>Diplopylidium</i> sp.) *2 (3.75 as drench, sheep)	2*Cestocur (Bayer), oral liquid (drench) for sheep, WT: sheep 0d, milk 0d Germany; WT: sheep 3d Australia	

(continued)

Cestodocidal Drugs, Table 1 (continued)

		with larval and adult stages of cestodes that have highly varied locations in the host; its major pathway of biotransformation is the liver; inactive drug metabolites are excreted mainly by the liver into bile and then feces; mode of action: the drug is rapidly taken up by cestodes and trematodes; however, uptake of PZQ is no guarantee of therapeutic activity (e.g., <i>F. hepatica</i> is unaffected by the drug); action of PZQ results in a rapid vacuolization of tegumental layer in the growth zone of the neck region of cestodes; vacuolization leads to disruption of the apical tegument layer (molecular mechanism leading to these alterations is not yet well understood); contraction (spastic and/or paralytic) of parasite musculature depends on drug concentrations used in isolated host tissue preparations; contraction of <i>Hymenolepis diminuta</i> muscle depends on endogenous Ca²⁺ (as in vertebrate skeletal muscle); contraction of <i>Schistosoma mansoni</i> muscle depends on uptake of external Ca²⁺ (as in vertebrate smooth muscle); tolerability: it is a safe drug after the oral or parenteral route; there is a wide margin of safety for PZQ as shown in acute and chronic toxicity studies in mice, rats, rabbits, and dogs; up to 5 times the recommended dose PZQ is tolerated without adverse effects in cats and dogs, 10-fold overdose may cause transitory vomiting and sign of depression; there was no evidence for embryotoxicity or teratogenicity in reproduction studies performed in rats, rabbits, cats, and dogs; the use of PZQ in breeding and pregnant animal is safe
Praziquantel (PZQ)/antinematodal drugs So called “allwormer” = drug combination with 2; 3; or 4 active nematocidal ingredients and PZQ for use in dogs and cats; for drug products cf. pyrantel, fenbendazole, oxfendazole, oxibendazole, febantel, abamectin, milbemycin oxime, emodeside; ► Nematocidal Drugs, Animals/Table 5	Drug products containing active nematocidal ingredients and PZQ for use in <i>sheep</i> and <i>lambs</i> cf. fenbendazole, abamectin, moxidectin (► Nematocidal Drugs, Animals/Table 1); drug products containing active nematocidal ingredients and PZQ for use in <i>horse</i> cf. pyrantel, ivermectin, abamectin, moxidectin (► Nematocidal Drugs, Animals/Table 3); *First Drench (Virbac Australia), liquid, WT 3d: levamisole HCl/ PZQ (7.5/3.8 mg/kg b.w.)	BZs (e.g., fenbendazole) and pyrantel affect certain flukes (cf. ► Trematocidal Drugs/Table 1) and cestodes; BZs may have good activity against <i>Taenia</i> spp. but not so against <i>Dipylidium caninum</i> in cats and dogs (cf. BZs ↓); pyrantel pamoate exhibits activity against the ileocecal tapeworm <i>Anoplocephala perfoliata</i> of horse at two times the recommended dose (13.2 mg/kg b.w.); the drug is inactive against common tapeworms in cats and dogs; a so called “allwormer” may contain a <i>macrocyclic lactone</i> (e.g., ivermectin, milbemycin oxime, or abamectin) BZ (e.g., fenbendazole, oxfendazole, or oxibendazole), pyrantel pamoate, praziquantel, and an <i>ectoparasiticide</i> (e.g., fipronil, imidacloprid, and/or s-methoprene or lufenuron); this group of drug products may involve a broad range of indications as relevant external and internal parasites (including prevention of heartworm disease) in cats and dogs, thus a single application of such kit-products may control not only all <11 > gastrointestinal worms but also common ectoparasites (fleas, ticks, and/or biting lice) of dogs; an example for an allwormer is < *The Complete Parasite Control Kit for Dogs 10–25 kg, Bayer, Australia > (active constituents: 0.8 g/L <i>ivermectin</i>, 100 g/L <i>imidacloprid</i>, 250 mg/Tb <i>febantel</i>, 50 mg/Tb <i>praziquantel</i>, 49.8 mg/Tb <i>pyrantel</i> as pamoate /embonate salt, <i>formulations</i>: topical solution and oral tablet) for the treatment and prevention of heartworms, fleas, and all “1” gastrointestinal worms; an allwormer may have various limitations/contraindications concerning the indication < prevention of heartworm disease > in regions where <i>Dirofilaria immitis</i> is endemic (for details cf. ► Nematocidal Drugs, Animals/Table 5/pyrantel)

Hydroxyzinebenzazepine	*Cestex (Pfizer AH, USA, Australia), oral tablets (various specifications: 12.5, 25, 50 or 100 mg/kg b.w. of epsiprantel) ESP/pyrantel pamoate: cf. ► Nematocidal Drugs, Animals/ Table 5/pyrantel	Chemically related to praziquantel (PZQ); since 1989 on the market (first USA, early 1990s Canada and Taiwan); unlike PZQ, it is poorly absorbed from the gastrointestinal tract and there seem to be no detectable metabolites in the urine of dogs; this puts the compound in a position to be in contact with tapeworms of the alimentary tract for a longer time; ESP is used for removal of common cestodes of dogs (<i>Dipylidium caninum</i>, <i>Taenia pisiformis</i>), and cestodes of cats (<i>D. caninum</i>, <i>T. taeniaeformis</i>: tapeworm segments may appear in feces for 2–3 days following treatment); if exposure to infected intermediate hosts is not controlled reinfection will be likely and so retreatment necessary; therefore, in cases of <i>D. caninum</i> infections an additional flea control program should be applied; immature/adult stages of <i>Echinococcus granulosus</i> are not completely eliminated by ESP (immature: 94, mature: 99 % at regular dosage of 5 mg/kg b.w.); total elimination of mature worms may be achieved with 7.5 mg/kg b.w.; there are no information on efficacy against other GI tapeworms in livestock; due to its low absorption from GI tract it is not likely that ESP may affect larval cestodes or flukes residing in liver or lungs; mode of action may be similar to that of PZQ; ESP may disturb regulation of Ca²⁺ and other cations leading to disintegration and lysis of tapeworm's tegument (cuticle) and digestion of the worm by the host; limitations: for oral use only as a single dose, do not use in animals less than 7 weeks of age; safety of use in pregnant or breeding animals has not been established; federal law restricts this drug to use by or on the order of a licensed veterinarian (USA., elsewhere); pregnant animals may be treated at mating, before birth of puppies or kittens and then every 3 months; tolerability: the drug is claimed to have a wide safety margin in dogs and cats; at 5 times the regular dose (once daily for 3 days) no adverse effects were observed; at 40 times the regular dose (once daily for 4 days) only slight clinical signs were seen
Epsiprantel (ESP)		
(5–5.5 dog, excluding under 7 weeks of age) (2.75 cat, excluding under 7 weeks of age)		
(<i>Echinococcus granulosus</i> : 7.5, not approved dose)		

Benzimidazole carbamates

Listed doses of benzimidazole carbamates (BZs) refer to <i>experimental studies</i> published in literature; BZs are primarily used for their efficacy against nematodes (► Nematocidal Drugs, Animals/ Tables 1, 3, 4, and 5); some of them are also effective against certain cestodes in animals like mebendazole (MBZ), fenbendazole (FBZ), oxfendazole (OFZ), albendazole (ABZ), or cambendazole (CBZ); BZs exhibit no activity against the common tapeworm <i>Dipylidium caninum</i> of cats and dogs; BZs have a wide margin of safety in livestock but their use is contraindicated (heavy incompatibility) within 7 days of a bromsalans flukicide administration in cattle (► Nematocidal Drugs, Animals/ Table 1)	
Dog and cats (adult stage or intestinal tapeworm, larval stage) <i>M. cori</i>	<i>Taenia</i> spp. of cats and dogs, good efficacy: MBZ (22, daily for 5 days), or: FBZ (50 daily for 3 days)
intermediate stage (tetrahyridium) of <i>M. cori</i> can infect dogs (final host)	<i>Echinococcus granulosus</i> in dogs, efficacy against adult stages: MBZ (20, 2 doses every 2 days)
	<i>Mesocostoides cori</i> in dogs, efficacy against adult stages: ABZ (50 every 12 h, 4 treatments, or 100 × 1)
	<i>Mesocostoides cori</i> larval stage (tetrahyridium) in dogs FBZ (100 twice daily for 14–60 days: 5 of 6 infected dogs were cleared); MBZ is also effective against tetrahyridia of <i>M. cori</i> in dogs

(continued)

Cestodocidal Drugs, Table 1 (continued)

Ruminants and chickens (adult stage or intestinal tapeworm) (larval stage of tapeworm in intermediate host)	<i>Moniezia</i> spp. infection in cattle/sheep, good efficacy at * regular dose: ABZ (*10*7.5), OFZ (*5), at enhanced dose FBZ (15), MBZ (20)
	<i>Thysanosoma actinoides</i> in sheep, efficacy against adult stages: FBZ (10)
	<i>Railletina tetragona</i> in chicken, good efficacy: OFZ (7.5 adults, 10 immature stages)
	<i>Cysticercus bovis</i> (larval stage of human tapeworm <i>Taenia saginata</i>),
	Marginal effect MBZ (5 daily for 10 days); marked (approx. total) reduction of cysts in beef tissue: FBZ (50), CBZ (35)
HORSE (adult stage or intestinal tapeworm)	<i>Cysticercus cellulosae</i> (larval stage of human tapeworm <i>Taenia solium</i>) reduction of cysts in pork: OFZ (single dose, cf. Gonzalez et al. 1996: <i>Am J Trop Med Hyg</i> 54: 391–394)
	Drug combinations containing macrocyclic lactones (ivermectin, abamectin or moxidectin) and praziquantel are approved for treatment of equine cestode infections caused by <i>Anoplocephala perfoliata</i> , <i>A. magna</i> , or <i>Paranoplocephala mamillana</i> , however, none of BZs products have been labeled for this indication, likely because of their insufficient efficacy against equine tapeworms at regular dose; enhanced dose MBZ (20) and FBZ was shown to be effective against <i>Anoplocephala</i> spp.
Laboratory animals (larval stage of tapeworm in intermediate host)	<i>Taenia cysticerci</i> in rabbits and pigs, marked (approx. total) reduction of visceral cysts: MBZ (25 daily for 5 days)
	<i>Echinococcus granulosus</i> , hydatid cysts in mice, marked (approx. total) reduction of visceral cysts: MBZ (150 intraperitoneally for 3 days) or FBZ (500 ppm in-feed for 18 weeks)

Antibiotics

Paromomycin (isolated in 1955, *Humatin) is a fermentation product of *Streptomyces rimosus* var. *paromomycinus* and commercially supplied as its neutral sulfate salt; first use as a cestocide was in Italy in 1963; in experimental studies, the antibiotic was shown to exhibit a promising effect against *T. taeniaeformis* in cats but not so against *Hymenolepis* spp. in rats and mice; in humans it proved to be effective against *Taenia saginata* and *T. solium* at doses of (40) for 5 days, or at (75); *Hymenolepis nana* infection in man was completely cured at doses of (40) for 7 days; its further use became limited because of the availability of modern drugs with simple regimens for patients; (cf. Table 2. relationship concerning antibacterial action of paromomycin and not its anticestodal efficacy; destruction of the basic functions of active molecule by N-acylation of primary amino groups results in complete loss of activity; its anticestodal action (*T. saginata*) may be based on fine-structural changes of the tegumental membrane making the tapeworm susceptible to digestive system of host; *Humatin (Parke-Davis, others) may be currently used for the treatment of asymptomatic *Entamoeba histolytica* infection of humans (cf. ► [Antidiarrhoeal and Antitrichomoniasis Drugs/](#)Table 1); it shows activity against gram-positive and gram-negative bacteria and may cause slight diarrhea after recommended dosage regimen

Data of drug products (approved labels) listed in this table refer to information from literature, manufacturer, supplier, and websites such as the European Medicines Agency (EMA), Committee for Veterinary Medicinal Products (CVMP), the U.S. Food and Drug Administration (FDA), Center for Veterinary Medicine (CVM), the Australian Pesticides and Veterinary Medicines Authority (APVMA) and associated Infopest (search for products), VETIDATA, Leipzig, Germany, and Clini Pharm, Clini Tox (CPT), Zurich, Switzerland.

Data given in this table have no claim to full information.

Cestodocidal Drugs, Table 2 Drugs used against cestode infections in humans

Parasite disease distribution, pathology	Stage affected (location), morphology of egg	Chemical class other information (1*, 2* etc. refer to linked chemicals and comments)	Nonproprietary name adult dosage (□ = pediatric dosage) (oral route), d = days, comments	Miscellaneous comments
Intestinal tapeworms:				
Adult worms consist of a head (scolex), a neck (growth region), and a strobila (series of proglottids)				
Diphyllobothriasis:				
First intermediate host is a copepod, second intermediate host are various freshwater fishes due to lack of specificity of the plerocercoid (sparganum lacking a bladder, see sparganosis); man becomes infected by ingestion of raw or undercooked fish-intermediate host containing plerocercoids; adult tapeworm may live for 25 years or longer in humans and may cause rarely vitamin B12 deficiency (due to absorption of B12 by the worm) and megaloblastic anemia; <i>D. latum</i> eggs (small knob at end, opposite the operculum) may be confused with those of <i>Paragonimus westermani</i> (cf. ► Trematodocidal Drugs/ Table 2)				
<i>Diphyllobothrium latum</i> (fish tapeworm), common where cold, clear lakes are abundant; occurs in N Europe, N America, Japan in fish-eating mammals, and man	Adult (5–15 m long) (upper half of intestine) eggs (unembryonated, ovoid, operculate, pass in feces into water)	1*pyrazino-isoquinolines contraindicated in ocular cysticercosis 2*halogenated salicylanilides (availability problems)	1*praziquantel (<i>drug of choice</i>) (5–10 mg/kg once, and □) <i>alternative:</i> 2*niclosamide (2 g once) (□ 50 mg/kg once)	1*safe and well tolerated, occasionally skin rashes 2*safe drug, also in pregnant or debilitated patient; occasionally abdominal pain, and pruritus
<i>Dipylidium caninum</i> (dog tapeworm)	Humans become infected by swallowing fleas containing infective larval stages (cysticercoids)			
Distribution worldwide; infrequent in humans, pathogenic effects are unknown; infection is due to close contact with infected dogs and their fleas	Adult (approx. 50 cm long) (small intestine) eggs (thin-shelled, small, spherical; contain 6-hooked onchosphere) pass in feces (typical egg packets each contains up to 15 eggs)	1*pyrazino-isoquinolines 2*salicylanilides (availability problems)	1*praziquantel (<i>drug of choice</i>) (5–10 mg/kg once, and □) <i>alternative:</i> 2*niclosamide (2 g once) (□ 50 mg/kg once)	Definite hosts (dogs, cats) should be regularly treated to avoid infection in humans (especially in children); eradication of fleas (pets carpets, rugs, and other sites) is needed
Hymenolepiasis:				
Humans become usually infected by ingestion of embryonated eggs (contaminated food and water); human infection also is possible by ingestion of arthropods (e.g., beetles) containing the infective larval stage (cysticercoid)				
<i>Hymenolepis nana</i> (dwarf tapeworm) occurs worldwide; infects simian primates, rodents, man; oncosphere can hatch also from embryonated egg within GI tract causing <i>autoinfection</i> ; this render eradication difficult; amounts of cysticercoids may damage intestinal mucosa and produce diarrhea	Adult (approx. 2–4 cm long) (lumen of small intestine; oncosphere develops in lamina propria of a villus to preadult cysticercoid) eggs (small, thin-shelled, spherical to subspherical, 6-hooked larva surrounded by a membrane with 2 polar “knobs” from which 4–8 filaments arise, pass in feces)	1*pyrazino-isoquinolines 2*salicylanilides 3*aminoglycoside (<1 % of dose is absorbed from gut, excreted unchanged in urine) 4*/5-nitrothiazole benzamide (first described in 1984 as a human cestodocidal drug)	1*praziquantel (<i>drug of choice</i>) (25 mg/kg once, and □) <i>alternative:</i> 2*niclosamide (2 g × 1 day; 1 g × 6 days) 3*paromomycin minimal side effects 4* nitazoxanide (500 mg × 3 days) (tablet = 500 mg) (investigational drug)	1* e.g., Biltricide is active against both juvenile and adult stages e.g., 2*Yomesan acts only against adults and mature cysticercoids, therefore treatment for 5–7 days 3* (40 mg/kg/day for 7 days) may cause total elimination of worm burden

(continued)

Cestodocidal Drugs, Table 2 (continued)

Parasite disease distribution, pathology	Stage affected (location), morphology of egg	Chemical class other information (1*, 2* etc. refer to linked chemicals and comments)	Nonproprietary name adult dosage (□ = pediatric dosage) (oral route), d = days, comments	Miscellaneous comments
4* nitazoxanide : there have been several reports on preclinical and clinical studies evaluating the activity of the drug against a broad spectrum of intestinal and extraintestinal parasitic infections including cryptosporidiosis, giardiasis, amebiasis, microsporidiosis, equine myeloencephalitis caused by <i>Sarcocystis neurona</i> (approved drug for horses = brand-name Navigator, IDEXX Pharmaceuticals, USA), ascariasis, fascioliasis, and other intestinal infections caused by protozoa such as <i>Balantidium coli</i> , <i>Blastocystis hominis</i> , <i>Isospora belli</i> , or helminths as whipworms, hookworms, and threadworm <i>Strongyloides stercoralis</i> (cf. Raether W, Haenel H (2003) Parasitol Res 90: S19–S39)				
<i>H. diminuta</i> (rat tapeworm) occurs worldwide; common parasite of rats, may occasionally infect man	Adult (20–60 cm long) (small intestine) eggs (large, thick-shelled, spherical, 6-hooked oncosphere, pass in feces)	Pyrazino-isoquinolines salicylanilides (availability problems)	Praziquantel (<i>drug of choice</i>) (25 mg/kg once) <i>alternative</i> : niclosamide (2 g × 1 days; 1 g × 5–7 days)	Clinical manifestations are inconspicuous (unknown)
Sometimes there may be diagnostic problems concerning confusion with <i>H. nana</i> eggs: oncosphere of <i>H. diminuta</i> is surrounded by a membrane without polar filaments and separated considerably from outer shell; rodent control and protection of food from insect intermediate hosts may prevent infection (infection may be acquired by accidental ingestion of infected beetles present in various grain products)				
Taeniasis:				
Humans become infected by ingestion of raw or undercooked muscles (beef or pork) containing infective cysticercus; <i>diagnostic problems</i> : eggs of human and animal taeniid species (<i>Taenia</i> and <i>Echinococcus</i> spp.) are all indistinguishable from each other; <i>T. saginata</i> and <i>T. solium</i> diagnostic is usually done by examination of gravid proglottids injected with India ink or stained by permanent stains to visualize characteristic number of lateral uterine branches (<i>T. saginata</i> : 15–30, and <i>T. solium</i> : 7–13); some pollen grains found in feces may closely resemble eggs of <i>Taenia</i> spp.; taeniid egg contains a characteristic 6-hooked embryo (oncosphere); caution should be used in handling unidentified gravid (mature) taeniid proglottids since <i>T. solium</i> and <i>Echinococcus</i> spp. eggs are infective to humans; they can cause larval tapeworm infections of brain, liver, lungs, and other organs (cf. larval tapeworm infections ↓)				
<i>Taenia saginata</i> (beef tapeworm), worldwide distribution (parallels stock keeping); adult worm causes no distinct lesions; cattle act as intermediate host	Adult (up to 8 m long) (upper half of small intestine) eggs (embryonated spherical, yellow-brown, thick shell striated radially, 30–44 μ Ø, pass in feces)	1* pyrazino-isoquinolines 2* salicylanilides (availability problems) 3* benzimidazole carbamates	1* praziquantel (<i>drug of choice</i>) (5–10 mg/kg once and □) <i>alternative</i> : 2* niclosamide (2 g once) 3* mebendazole , Vermox (200 mg BID × 3 days)	In most cases there are no clinical signs; on an individual level, infection can be prevented by thorough cooking of meat or by freezing meat at –18 °C for 7 days
<i>T. solium</i> (pork tapeworm), worldwide distribution (parallels pig keeping); pigs and humans act as intermediate host; they become infected with embryonated eggs by ingestion of contaminated food or by <i>autoinfection</i>	Adult (up to 6 m long) (small intestine) eggs (morphology cf. “Taeniasis”, and <i>T. saginata</i> ↑, pass in feces; egg of <i>T. solium</i> may be infective to humans and can cause cysticercosis)	1* pyrazino-isoquinolines (1* has a moderate effect on larval stages) 2* salicylanilides 3* benzimidazole carbamates	1* praziquantel (<i>drug of choice</i>) (5–10 mg/kg once and □) <i>alternative</i> : 2* niclosamide (2 g once) 3* mebendazole (200 mg BID × 3 days)	2* has no ovicidal action on larvated egg; larva liberated from a shed gravid segment in upper intestine can cause cysticercosis; do not use a purgative; an enhanced peristalsis increases risk of cysticercosis

Larval tapeworms:

(continued)

Cestodocidal Drugs, Table 2 (continued)

Parasite disease distribution, pathology	Stage affected (location), morphology of egg	Chemical class other information (1*, 2* etc. refer to linked chemicals and comments)	Nonproprietary name adult dosage (□ = pediatric dosage) (oral route), d = days, comments	Miscellaneous comments
There are two types of larvae invading human tissues, (1) larva with a bladder, and (2) larva lacking a bladder (sparganum)				
Larval cestode diseases:				
Man may be infected by ingestion of an oncosphere-containing (embryonated) egg or by ingestion of a larval stage belonging to the genus <i>Spirometra</i> (cf. sparganosis ↓)				
Cysticercosis, neurocysticercosis contaminated food containing <i>T. solium</i> eggs may infect humans during meal; <i>autoinfection</i> is possible; cysticerci with a fibrous tissue capsule may undergo calcification and release antigens that can cause inflammatory reactions				
<i>Taenia solium</i> (larva type: a single scolex invaginated into a bladder) cerebral cysticercosis may occur where pig keeping is done; (prevention of infection cf. "Taeniasis" ↑)	Cysticercus cellulosae larva may reside in almost any tissue, often brain: larva tends to grow slowly to a large cyst that causes space-occupying lesions and/or hydrocephalus (larva in ventricle blocks CSF circulation)	1*benzimidazole carbamates 1*Eskazole, Albenza, others 2*pyrazino-isoquinolines 2*Biltricide experimental drugs: <i>mebendazole</i> <i>flubendazole</i>	Treatment of choice (see below) <i>alternative:</i> 1*albendazole (ABZ) (400 mg BID × 8–30 days, can be repeated as necessary) 2*praziquantel (PZQ) (50–100 mg/kg/day in three doses for × 30 days)	Treatment of choice (see below) <i>alternative:</i> 1*albendazole (ABZ) (□15 mg/kg/day, <max. 800 mg > in two doses × 8–30 days; can be repeated as necessary) 2*praziquantel (PZQ) (□50–100 mg/kg/day in three doses for × 30 days)
Treatment of choice of parenchymal cysticercosis: initial therapy for patients with inflamed parenchymal cysticercosis should focus on symptomatic treatment with anti-seizures medication; treatment of parenchymal cysticerci with ABZ or PZQ is controversial and characterized by various limitations: (1) patients with live parenchymal cysts and seizures should be treated with ABZ together with steroids (dexamethasone: 6 mg or prednisone: 40–60 mg daily) and an antiseizure medication; (2) patients with subarachnoid cysts or giant cysts in the fissures should be treated with ABZ for at least 30 day; (3) patient with arachnoiditis, vasculitis, or cerebral edema: prednisone 60 mg/day or dexamethasone 4–6 mg/day together with ABZ or PZQ; contraindication: any cysticercocidal drug may produce irreversible pathologic alterations when used to treat <i>ocular or spinal cysts</i> even with concurrent use of steroids; (4) in case of obstructive hydrocephalus surgical intervention or cerebrospinal fluid (CSF) diversion is indicated (prednisone 40 mg/day may be given with surgery); surgical excision of accessible lesions is the only reliable means of cure and should include the use of anticonvulsant drugs; chemotherapy of neurocysticercosis is further discussed to define guidelines for use of drugs in inoperable patients				
Coenuriasis (infrequent): adult worm occurs in Canidae like dog, fox, coyote, and others (definitive hosts); herbivores serve as intermediate hosts as cattle, horse, sheep, wild herbivores, rarely man; latter becomes infected by ingestion of contaminated food containing embryonated eggs; human <i>Coenurus cerebralis</i> -disease mainly occurs in Africa; space-occupying larva usually invades brain				
<i>Taenia multiceps</i> (= <i>Multiceps multiceps</i>) (larva type: multiple invaginated scoleces into a bladder), infrequent	Coenurus cerebralis , larval cyst contains several hundred proto-scoleces (central nervous system, usually brain)	Prevention is not possible (reservoir hosts include numerous species of wild carnivores)	Drug medication is unknown against space-occupying lesions due to larva	Only reliable means is excision of accessible cyst

Cystic hydatid disease (hydatidosis, or cystic echinococcosis = CE): *Echinococcus granulosus* larva-type is a *unilocular hydatid cyst* infection of intermediate host (usually sheep, other herbivores as cattle, horse, and occasionally man) is due to close contact with dogs and other canids (definitive hosts), which may be infected with large numbers of adult worms (3–6 mm long, with a single gravid proglottid that is longer than wide; it contains typical *Taenia*-like eggs); feces of dogs contain embryonated eggs infective to potential intermediate hosts (occasionally humans); cestode larval stage in human tissues is characterized by multiple daughter bladders or "brood capsules" with multiple invaginated

(continued)

Cestodocidal Drugs, Table 2 (continued)

Parasite disease distribution, pathology	Stage affected (location), morphology of egg	Chemical class other information (1*, 2* etc. refer to linked chemicals and comments)	Nonproprietary name adult dosage (□ = pediatric dosage) (oral route), d = days, comments	Miscellaneous comments
protoscoleces budding from their walls (inner layer of germinal epithelium of cystic cavity); cyst content (materials) consisting of degenerated scoleces and debris in milky fluid of parent cyst is referred to as <i>hydatid sand</i> (calcareous corpuscles)				
<i>Echinococcus granulosus</i> (humans are an accidental intermediate host and are usually infected by handling an infected dog)	Hydatid cyst, unilocular (solitary or multiple or oval masses on imaging, frequently seen in liver and lungs, but also other tissues)	1*benzimidazole carbamates mebendazole (40–50 mg/kg/day in 3 divided doses is less efficacious than albendazole in long-term regimen)	1*albendazole (<i>drug of choice</i>), (400 mg bid × 1–6 months) praziquantel preoperatively use cf. ↓	1*(□ 15 mg/kg/day, <max. 800 mg > × 1–6 months); adverse effects include nausea, hepatotoxicity, neutropenia, rarely alopecia (long-term treatment)

Sheep and cattle are common intermediate hosts of the larval stage; prevention of hydatidosis may be largely achieved if abattoir and disposal of infected offal are strictly controlled [for details cf. Raether W, Haenel H (2003) *Parasitol Res* 91: 412–438]; most ultrasound surveys of CE reveal that the zoonotic sheep strain of *E. granulosus* is likely the main cause of human CE in remote rural areas; clinical symptoms and manifestations in CE patients are highly variable and often nonspecific; infected individuals may be asymptomatic for a long time, symptoms may result from release of antigenic material following cyst rupture and dissemination of viable scoleces (secondary infection); there is a great diversity of clinical manifestations and pathological alterations in liver and lungs and other organs; about 20–40 % of CE patients have multiple cysts with involvement of several organs; total surgical resection of an hydatid cyst may be still considered the < gold standard treatment > for CE; medical treatment with benzimidazole drugs is currently used in nonsurgical cases or as supplementary treatment prior to and post-surgery to reduce the risk of secondary CE (intraoperative spillage of viable material) and recurrence; WHO recommends postoperative chemotherapy (in case of spillage of protoscoleces) for at least 1 month with albendazole (ABZ) or 3 months with mebendazole (MBZ); **praziquantel** (PZQ) may be useful preoperatively in case of cyst spillage during surgery; it has also been used (25 mg/kg/day) with ABZ for combined treatment of CE resulting in improved efficacy over ABZ alone (PZQ may increase serum concentrations of ABZ sulfoxide up to four-fold); percutaneous aspiration-injection-reaspiration (PAIR) with ultrasound guidance plus ABZ treatment has been effective for management of hepatic CE; however, for PAIR there is no ideal agent that is both effective and safe; for optimum efficacy, scolecidal compounds require a 15 min “dwell time” within the cavity; relatively safe and effective are ethanol (70–95 %), saline (15–20 %) and cetrimide solution (formalin should never be used); severe, sometimes fatal chemical (sclerosing) cholangitis can result if there is communication between biliary tree and cyst; in summary, there is yet no formal consensus, as efficacy and safety of the methods require further evaluation to establish comprehensive guidelines for medical treatment of CE; ABZ and MBZ (teratogenic in laboratory animals) are listed as category C drugs in pregnancy in the USA (in Australia category D; B3); neither drug is absolutely contraindicated in pregnancy

Alveolar disease (or alveolar echinococcosis = AE): *Echinococcus multilocularis* larva-type: *multilocular* or *alveolar multilocular* cyst large numbers of adult worms (3–5 mm long, morphology cf. *E. granulosus*, and eggs of taeniid type) primarily occurring in fox (definitive host, occasionally dogs, cats, and wolves); several microtine rodents serve as intermediate host (sylvatic cycle); major source of infrequent human infection is through fruits and vegetables contaminated with larvated eggs from fox feces; in infected humans, “metastasis” (branches) of the laminated membrane by the alveolar cyst resembles lesion of a neoplasm; lesions in the liver are usually membranous; in contrast to hydatid of *E. granulosus*, neither protoscoleces nor hydatid sand (calcareous corpuscles) are identifiably in human cysts

<i>Echinococcus multilocularis</i> (infrequent); <i>E. vogeli</i> (infrequent) causing polycystic echinococcosis	Growth of alveolar (multilocular) cyst is peripheral and invasive; metastases are frequent (liver, adjacent tissue)	<i>Experimental drugs:</i> (flubendazole, fenbendazole, oxfendazole, amphotericin B <i>nitazoxanide</i>)	Treatment if early diagnosed, surgical excision of lesions is a reliable means of treatment	No therapy is fully effective against tumorlike growth of alveolar type of cyst
---	--	--	--	---

Clinical manifestation produced by the alveolar larva of *E. multilocularis* are related to the extent of tumorlike lesions of the cyst; AE is characterized by a chronic course lasting for months or years; clinical symptoms are variably and usually

(continued)

Cestodocidal Drugs, Table 2 (continued)

Parasite disease distribution, pathology	Stage affected (location), morphology of egg	Chemical class other information (1*, 2* etc. refer to linked chemicals and comments)	Nonproprietary name adult dosage (□ = pediatric dosage) (oral route), d = days, comments	Miscellaneous comments
only follow a long asymptomatic period (5–15 years); in liver, alveolar hydatid presents a mass- producing inflammatory process; metastasis in lungs may be seen as multiple small solid foci and pathological findings may be characterized by marked foreign-body reaction in bones; treatment: AE is difficult to treat; current treatment approach is preferable surgery, or secondarily benzimidazole chemotherapy; radical surgical resection of complete alveolar lesion(s), e.g., in right or left liver lobes, is the only potential curative treatment [cf. details Craig P (2003), <i>Curr Opin Dis</i> 16: 473–444]; albendazole (ABZ: 10–15 mg/kg/day: long-term treatment: 6.5 years) is the drug of choice for human AE in patients with nonresectable AE; ABZ may be a useful adjunct therapy to surgery; overall its use orally resulted in improved 10-year survival rates up to 80–83 % compared to 6–25 % for untreated historical controls [a WHO group recommended long-term treatment: 3–24 months: ABZ (10 mg/kg), mebendazole (40–50 mg/kg); high doses are necessary to affect larva WHO Group Bull WHO, 74:231, 1996]; nitazoxanide (NTZ)-treated in vitro cultured metacestodes of <i>E. multilocularis</i> were nonviable when implanted into susceptible mice; as NTZ is much better absorbed than ABZ following oral administration it provides an attractive alternative for medical treatment of human AE Sparganosis: larva type: solid-bodied larva lacking a bladder adult worm (pseudophyllidean tapeworm) occurs in cats, dogs, wild canids, or felids and is of little significance to definitive hosts; first intermediate host is a copepod, second one any vertebrate due to lack of specificity of the plerocercoid; humans become infected (1) by ingestion of a copepod (crustaceans) containing procercoids (first larval stage), (2) by ingestion of raw or undercooked flesh or organs of any vertebrate (amphibians, reptiles, mammals, particularly feral pigs raised for human consumption) containing plerocercoids (=sparganum, second larval stage, easily mistaken for nerves), or (3) by local application of flesh (poultice to wounds or to the eye) containing plerocercoids sparganum				
<i>Spirometra</i> spp. (infrequent), life cycle is similar to that of <i>D. latum</i> (fish tapeworm of humans)	Procercoid (migrate in subcutaneous and muscular tissue) plerocercoid (migrate in connective tissue of muscles, abdomen, hind legs; peritoneum, pleura)	There is no reliable chemotherapy (<i>praziquantel</i> may show some larvicidal effects)	<i>Treatment</i> is surgical prevention is difficult because of entrenched eating habits and other customs	Larval worms cause during subcutaneous migration painful edema, urticaria, inflammation, fibrosis; spargana grow into irregular nodules of subcutaneous tissues

Abbreviation: *BID* bis in die = twice a day

Dosages listed in the table refer to information from manufacturer, literature, and/or Medical Letter (2004) “Drugs for parasitic infections”: The Medical Letter (publisher) 46 (issue 1189): e1–e12, New Rochelle, New York.

Data given in this Table have no claim to full information.

(suckers = acetabula), which may be armed with hooks and a rostellum with two rows of hooks. Transmission of many important cestodes in livestock, such as *Taenia* spp. and *Echinococcus* spp., usually involves “predator – prey” relationships between carnivores or omnivores (e.g., man) acting as final hosts and herbivores (food animals, occasionally man) serving as intermediate hosts. Food animals like ruminants and horses may also acquire adult tapeworms (*Moniezia* spp. or *Anoplocephala* spp.) by ingestion of arthropod intermediate hosts (mites of the family Oribatidae) with herbage. Large numbers of *A. perfoliata* and *A. magna* may cause clinical signs in horses and donkeys, e.g., catarrhal or

hemorrhagic enteritis, ulcerative lesions, and occasionally perforation of the intestine. Although lambs, kids, and calves under 6 months of age may be substantially infected with *Moniezia* spp.; pathogenic effects of these tapeworm infections appear to vary considerably. Major economic impact may result from **zoonotic infections** caused by members of the family of Taeniidae (*Taenia* spp., *Echinococcus* spp.). Close contact of humans, dogs, and foxes (final hosts) with feedlot cattle and other ruminants, rodents, and by chance, humans, acting as intermediate hosts can lead to larval tapeworm infections. Thus, humans infected with *T. saginata* may pass thousands of eggs daily, which may be

transmitted to cattle directly in feed or water or via pasture. Pigs running loose scavenging for food and with easy access to human feces may become infected by ingestion of gravid proglottids. Invertebrates such as blowflies, beetles, or earthworms may disperse *Taenia* spp. eggs, and they will remain viable for about 6 months. Cysticerci such as *Cysticercus bovis* (infectious stage of *T. saginata*) or *C. cellulosae* (infectious stage of *T. solium*) develop primarily in skeletal and cardiac muscle. **Neurocysticercosis** of humans may occur by ingestion of *T. solium* eggs with contaminated food or by **autoinfection**. Autoinfection is possible if eggs are released in the upper intestine, and regurgitated into the stomach. Oncospheres released from digested eggs then reenter the intestine where they initiate the life cycle.

Economic loss in livestock may result also from condemnation of carcasses or offal as unsuitable for human consumption at the abattoirs. For instance, *C. bovis* in the musculature of cattle becomes infective about 10 weeks after infections and remains viable for up to 9 months. Humans become infected by the ingestion of raw or undercooked infected beef (Table 2). Despite the availability of more sensitive and specific immunodiagnostic tests (recombinant antigens, PCR techniques) their role for routine diagnosis of cysticercosis in cattle will be very limited. Such tests could be used, however, on a herd basis to find out whether a herd is free of cysticerci or infected. This would be a valuable approach in ► **epizootiology** of ► **cysticercosis**. Today there are no effective drugs, which may be used economically in the treatment of ► **metacestode** infections in livestock. **Prophylactic measures** should therefore always involve treatment of infected persons and management adjustments such as proper meat inspection. However, the latter measure is estimated to detect only about 50 % of the infected carcasses. To kill cysticerci, beef carcasses must be frozen, e.g., for 6 days at -20°C , or carcasses should be cooked. There are several reports that cattle and sheep (goats) can be successfully vaccinated against *T. ovis* and *T. saginata* (beef tapeworm) with recombinant antigens inducing high levels of protective immunity. This may give some hope for the commercial

use of such vaccines against infection in the near future (cf. ► **Vaccination**).

Through chemotherapy, complete elimination of *Echinococcus* spp. infections in dogs must be achieved because of the major agricultural and public health problems due to hydatidosis in intermediate hosts. Primarily sheep but also other herbivores such as goats, cattle, horses, camels (pigs), and by chance humans serve as intermediate hosts. There are phylogenetic variations in *Echinococcus*, i.e., several strains of *E. granulosus* differing in their morphology and their isoenzyme patterns. Some of these strains appear to be specific for a particular intermediate host and an endemic area. The horse strain does not appear to infect humans although the sheep strain does. Human hydatidosis (infectious stage of *E. granulosus*, cf. Table 2) is often associated with severe clinical signs, particularly if the brain (hydatid cyst with calcifications) or heart is involved. This is also true in human alveolar cyst formation caused by *E. multilocularis* and *E. vogeli* (Table 2). Hydatidosis in domestic animals rarely produces clinical signs despite heavy infections. Adult *E. granulosus*, only 3.5–5.6 mm in length, is principally harmless to the dog although large numbers of adults may cause enteritis. There has been substantial progress toward successful vaccination against *E. granulosus*; recombinant antigens from *E. granulosus* generated more than 95 % protection against challenge in vaccinated sheep or dogs.

Old Remedies and Modern Compounds with Cestocidal Activity

There are many old remedies showing some activity against adult tapeworms. Thus pumpkinseeds, powdered areca (fruits of betel palm, *Areca catechu*), kousso (flowers of an Abyssinian tree, *Hagenia abyssinica*), turpentine (oily mixture of exsudates from coniferous trees, especially longleaf pine), pomegranate root bark (tropical Asian and African tree, *Punica granatum*), and male fern (*Dryopteris filix-mas*) were used as anticestodal remedies. These and other plant products had been gradually replaced by arecoline

(alkaloid obtained from seeds of betel palm), organic tin compounds, lead arsenate, or dichlorophene during the first half of this century. Since 1921, **arecoline** has been used in veterinary medicine for many years against *E. granulosus* and *Taenia* spp. in dogs. Because of its relative low efficacy and its severe side effects, it is no longer recommended as a therapeutic drug in dogs and cats. However, its strong parasymphathomimetic action causes purging and thus partial removal of paralyzed worms from the intestine. This action makes arecoline a useful diagnostic agent, which may give valuable information on whether a group of dogs on a farm is infected with *Taenia* spp. or *Echinococcus* spp. or not.

Several “modern” **synthetic compounds** are in current use for the control of tapeworm infections preferably in pets (Table 1). Such drugs are for instance dichlorophene, bunamidine, niclosamide, resorantel, benzimidazole carbamates, nitroscanate, pyrantel (e.g., horses), praziquantel, and epsiprantel. They may exhibit good activity against adult stages of intestinal tapeworms while praziquantel (Table 2) and benzimidazole carbamates (mebendazole, albendazole) show action against larval stages of certain cestodes. Thus, mebendazole and albendazole may improve clinical illness of ► **hydatid disease** (*Echinococcus* spp.) in humans following long-term treatment.

Drugs Acting on Adult Tapeworm Infections in Dogs and Cats

Echinococcus spp., *Dipylidium caninum* (highly active proglottids may cause anal irritation and thus scooting), *Diphyllobothrium latum*, and *Spirometra* spp. have public health implications (Table 2). Other cestodes occurring in dogs and cats are *Taenia* and *Mesocestoides*. Routine treatment with effective cestocidal drugs at intervals less than the prepatent periods of the parasites should be used in working dogs to reduce the incidence of *Echinococcus* spp. infections, particularly in rural areas. Other control measures should also be considered to prevent hydatidosis in livestock and man, such as control of home slaughtering of small ruminants and consequent

condemnation of infected viscera of infected animals, and quarantine regulations for dogs.

The majority of compounds recommended for treatment in dogs and cats (Table 1), such as bunamidine HCl, some benzimidazole carbamates (e.g., mebendazole, fenbendazole), niclosamide, praziquantel, and epsiprantel, prove highly effective against adult stages of *Taenia* spp. and *D. caninum*. The action of **niclosamide** is, however, somewhat erratic against *D. caninum*. **Bunamidine** appears to be the only drug that shows efficacy against *Spirometra* spp., particularly against *S. erinacei* in dogs and cats. Like praziquantel, it also exhibits activity against *Mesocestoides* spp. but requires a ten times higher dosage than that drug. **Nitroscanate**, introduced in 1973 (not commercially available in Germany, USA, Australia) as a broad-spectrum agent for use in dogs, has marked activity against roundworms (*Toxocara canis*, *Toxascaris leonina*), hookworms (*Ancylostoma caninum*, *Uncinaria stenocephala*), and tapeworms (*Taenia* spp. and *D. caninum*). However, the drug is not recommended for use against *E. granulosus* infection since 100 % elimination of adults and juvenile worms is not achievable. **Praziquantel** (Tables 1 and 2) is a safe and highly active drug against a broad range of mature and immature tapeworms (including *Echinococcus* spp.), and most trematodes (particularly *Schistosoma* spp. cf. ► **Trematodocidal Drugs**). **Epsiprantel** one of the latest cestocidal products on the market is chemically related to praziquantel. It exhibits good activity against common tapeworm infections in cats (*D. caninum* and *Taenia taeniaeformis*), and dogs (*T. pisiformis* and *D. caninum*), and shows an excellent action on adult *E. granulosus*. The drug is poorly absorbed from the gastrointestinal tract allowing the compound to be in contact with the parasites for a prolonged period.

There are numerous combinations of praziquantel with antinematodal compounds (cf. ► **Nematocidal Drugs, Animals**), e.g., **febantel/pyrantel/praziquantel** (Drontal Plus for dogs), an all wormer against intestinal nematodes and cestodes or **praziquantel/pyrantel** (Drontal for cats) has a high activity against

Ancylostoma caninum and cestodes but only moderate activity against *Toxocara canis* and *Trichuris vulpis*. **Albendazole/praziquantel** may control various tapeworm infections (*Taenia* spp., *D. caninum*, *Echinococcus* spp.) and nematode infections (roundworms such as *Toxocara* spp., hookworms as *Ancylostoma* spp., the whipworm *Trichuris vulpis*, and *Strongyloides* spp.). **Ivermectin/praziquantel** may be used for heartworm prophylaxis (*Dirofilaria immitis*) and prevention of tapeworm infections in dogs (cf. pyrantel Table 1 for details).

Drugs Acting on Adult and Larval Tapeworm Infection of Sheep and Cattle

There are several species (e.g., *Moniezia expansa*, *M. benedeni*, *Avitellina* spp., and *Thysaniezia giardi*) which occur in the intestine of sheep, goats, cattle, and other ruminants in most parts of the world. *Stilesia hepatica* and *Thysanosoma actinioides* (the fringed tapeworm) are found in the bile ducts of cattle, sheep, and wild ruminants (e.g., deer) in Africa and Asia, or in North and South America (*T. actinioides*). None of these relatively large species appears to be very pathogenic, and therefore there may only be economic return from treatment of lamb and calves if the administered compound is effective against both cestodes and nematodes. Such drugs include the **benzimidazole carbamates** (e.g., albendazole, oxfendazole); they exhibit good efficacy against various intestinal nematodes (► [Nematocidal Drugs, Animals](#)) and cestodes (Table 1) in food animals. **Niclosamide** exerts good activity against *Moniezia* spp. and *Avitellina* spp. in ruminants. **Albendazole**, **fenbendazole**, and **praziquantel** are effective against cestodes occurring in the bile ducts. However, enhanced doses (double and four times the recommended dose) of these drugs are necessary to eliminate the tapeworms.

High doses of praziquantel (20–40 times the recommended dose) are required to affect *T. saginata* or *T. hydatigena* **larval stages** in cattle and sheep; cost for treatment precludes, however,

the use of praziquantel in the field. The same is true for albendazole showing action on larval *T. saginata* in cattle at ten times the recommended dose. The mode of action of the **benzimidazole carbamates** is generally thought to be primarily due to alterations in microtubule polymerization via a direct binding of these compounds to parasite tubulin. Thus, the coadministration of **fenbendazole** and the phenylguanidine **netobimin** (a prodrug of albendazole, cf. ► [Nematocidal Drugs, Animals](#)) has been shown to inhibit solidly the regenerative capacity of hydatid material in gerbils. Recurrence of hydatid-cyst never took place when using coadministration of both drugs. Different effects have been observed after the administration of **praziquantel** in laboratory animals against larval stages of *Echinococcus*. Thus it affects protoscoleces of *E. multilocularis* but does not inhibit growth of cysts of both *E. multilocularis* and *E. granulosus*.

Drugs Acting on Adult Tapeworm Infections in Horses and Donkeys

Clinical signs associated with tapeworms in equines are uncommon. Occasionally *Anoplocephala magna* and *Paranoplocephala mamillana* occurring in the small intestine and rarely stomach may cause catarrhal (rarely hemorrhagic) enteritis. *A. perfoliata* found in the large and small intestine is often localized near the ileocecal orifice and ulcerative lesions and edema may be produced where the scoleces are attached to the cecal wall. Clinical signs (e.g., diarrhea) are usually seen in autumn and spring when infected oribatid mites may be present in great numbers. Because of the low pathogenicity of these tapeworms, treatment should be considered carefully since use of a compound that acts only specifically is unlikely to be economic. It may be of value to use a compound that combines activity against both cestodes and nematodes. Thus, **pyrantel embonate** (an antinematodal agent, cf. ► [Nematocidal Drugs, Animals](#)) has

been found to have a distinct activity against *A. perfoliata* at twice the nematocidal dose. It is only variably active against *P. mamillana*. However, in confirmed cases of equine cestodiasis **praziquantel** (1 mg/kg: *P. mamillana*; 0.5 mg/kg: *A. perfoliata*) exhibited a marked effect against these tapeworms. **Fenbendazole** (3×10 –20 mg/kg) and *mebendazole* (dosage see Table 1) also show action on equine tapeworms (cf. also ► [Nematocidal Drugs, Animals](#)). However, widespread benzimidazole resistance of equine nematodes may limit the economic value of such a therapy. **Niclosamide** (80–100 mg/kg b.w., not approved indication, availability problems) had good activity against anoplocephalids of all ages. Combinations containing praziquantel and a macrocyclic lactone (ivermectin, abamectin, or moxidectin, cf. ► [Nematocidal Drugs, Animals](#)) may be used for the prevention and control of infections caused by cestodes, nematodes, and *Gasterophilus* spp. (botflies).

Drugs Acting on Adult Tapeworm Infections in Birds

In the poultry industry the meat production has increased continuously worldwide (cf. ► [Coccidiocidal Drugs/Economic Importance](#)). In 2004, broiler meat production amounted to about ten million metric tons in the USA and China, respectively (USDA, Vol. 08 NO. 45, 2005). In birds, losses due to moderate and seldom heavier tapeworm infections may be diarrhea (enteritis), weight depression, emaciation, and rarely mortality. Free-range birds, e.g., those in backyard flocks, and cage birds in aviaries with earthen floors are often hosts to many species of tapeworms (e.g., ► *Davainea proglottina*, *Raillietina* spp., *Cotugnia* spp., *Amoebotaenia cuneata*, *Choanotaenia infundibulum*, *Hymenolepis* spp., *Fimbriaria* spp., and other cestodes). Their life cycles require the development of cysticercoids (larval stages) in a large number of intermediate hosts such as various copepods,

snails, and insects. Modern husbandry methods may largely prevent access to the various intermediate hosts, thus preventing tapeworm infections in commercial poultry. Consequently, only little information is available about adequately tested compounds in birds. **Niclosamide** (250 mg/kg, per os) seems to be effective and safe in most cases (can be toxic to geese). **Praziquantel** (5–10 mg/kg) is effective against a wide range of immature and mature cestodes in poultry, waterbirds (ducks, geese), and game birds (pheasant, partridge). However, an economic return to its use seems to be questionable. **Benzimidazole carbamates** (fenbendazole, mebendazole, other compounds, ► [Nematocidal Drugs, Animals](#)), exhibit variable actions on avian cestodes. Fenbendazole is somewhat erratically effective against *Davainea proglottina*, and the activity of mebendazole is limited to *Raillietina* and *Hymenolepis*.

Drugs Acting on Adult and Larval Tapeworm Infections of Humans

Among the adult (intestinal) tapeworms in man, *T. solium* (pork tapeworm, common in Latin America) and *D. latum* (broad tapeworm or fish tapeworm, common in regions where freshwater fishes occur) are particularly important to human health. *T. solium* may cause ► [cysticercosis](#) (Table 2) and *D. latum* pernicious anemia due to vitamin B₁₂ deficiency. Other adult tapeworm species affecting humans are *T. saginata* (beef tapeworm, worldwide distribution, approx. 60 million people currently infected), and *Hymenolepis nana* (dwarf tapeworm, infects not only man but also mice and rats). *T. saginata* may cause economic loss due to taeniasis or cysticercosis in cattle and *H. nana* play a role as zoonosis since cross-infections between humans and rodents are possible. Mainly two drugs, the older **niclosamide** (a nitrosalicylanilide) and the newer **praziquantel** (pyrazinoisoquinoline) are used for elimination of these tapeworms from the intestinal tract (dosage, cf. Table 2). Old remedies (certain

seeds from locally grown plants) or other drugs may still be in use (Tables 1 and 2).

Larval cestodes of certain tapeworms lodge preferably in the central nervous system, or in the liver (lung or other organs). Thus the cysticercus of *T. solium* causes neurocysticercosis. The hydatid cyst of *E. granulosus* produces cystic ► **echinococcosis**, and that of *E. multilocularis* alveolar echinococcosis. *E. vogeli* causes polycystic echinococcosis in humans, and characteristics of *E. vogeli* metacestode are considered intermediate to those of *E. granulosus* and *E. multilocularis*. Because of the tumor-like growth and proliferation of larval stages, clinical manifestations and pathology are characterized by their great diversity of moderate to severe symptoms. **Treatment** of diseases caused by larval stages is based mainly on three measures focusing on symptomatic and causal therapy: (1) Palliative drugs (e.g., antiepileptics and corticosteroids) are used to control seizures and inflammation associated with tissue reactions caused by cestode larva. (2) Measures of palliative surgery are performed to drain CSF by placement of ventricular shunts, and those of causative surgery to remove solitary brain cysticerci or hydatid cyst from liver or lung. (3) Long-term chemotherapy (indicated if surgical resection of cyst is not possible) may result in complete and permanent disappearance of cyst if it is surrounded by minimal adventitial reactions. Patients with complicated cysts (multiple compartments and numerous daughter cysts) and surrounded by solid fibrous reactions appear to be considerably refractory to treatment (drugs used see Table 2). Children suffering from larval cestode infection usually respond more sensitively to chemotherapy than adults. **Albendazole** and **praziquantel** may be useful for affecting and eliminating living cysticerci in brain parenchyma and in the subarachnoid space. **Antiepileptic drugs** are the treatment of choice for patients suffering from epileptic attacks caused by neurocysticercosis with calcifications. The administration of such drugs is indicated when seizures are the only manifestation of the disease and there is no imaging and immunological evidence of

living parasites. **Corticosteroids** should be used simultaneously with chemotherapy (for 2 or 3 days prior to and during drug treatment) to reduce exacerbation of neurological symptoms. Any cysticercocidal drug may cause irreparable damage when used to treat ocular or spinal cysts, even when steroids are used. An ophthalmic examination must be carried out before treatment. **Surgical removal** of cystic echinococcosis (*E. granulosus*) appears to be the treatment of choice if cysts are large (>10 cm Ø). When surgical excision cannot be performed because of general condition of the patient and the extent and location of the cyst, **long-term chemotherapy** should be performed either with **albendazole** (10 mg/kg, b.w.) or **mebendazole** (40–50 mg/kg, b.w.) for at least 3 months. These benzimidazole carbamates also inhibit the growth of larval *E. multilocularis*, reduce metastases, and may enhance both the quality and length of patient's survival. Sometimes they may be larvicidal after prolonged therapy but often recurrence may occur.

Alveolar hydatid disease (*E. multilocularis*) is often diagnosed too late so that lesion becomes inoperable. This may also be true for surgical resection of extensive lesions caused by polycystic echinococcosis (*E. vogeli*). Liver transplantation has been successfully performed on otherwise terminal cases. Often combination of surgery with chemotherapy (albendazole) is more likely to be successful in cases in which resection is difficult and usually incomplete. Post-operative chemotherapy should be done routinely for at least 2 years after radical surgery. Also prolonged follow-up of patients for at least 10 years with ultrasound or other imaging procedures is necessary to track down possible recurrence of cysts. Combined methods of percutaneous cyst puncture and drainage under ultrasound guidance can be carried out with or without injection of a protoscolicidal compound (e.g., 95 % ethanol, or 20 % sodium chloride solution). Thus liquid cyst content is aspirated (or drained), the chemical installed, and then re-aspirated (or drained). Secondary

echinococcosis, which may be caused by accidental spill of cyst fluid during this procedure, can be minimized with simultaneous administration of albendazole or preoperative use of praziquantel. Ivermectin directly injected into hydatid cyst of *E. granulosus* has been found to damage viable protoscoleces in gerbils 6–8 weeks after injection. “Percutaneous drainage, i.e., aspiration-injection and re-aspiration” (= PAIR) should be performed only if cysts have no biliary communication. Otherwise, sclerosing cholangitis may occur when the chemical is installed. Therefore prior to PAIR, cyst fluid has to be investigated for the presence of bilirubin.

Düsseldorf, Germany

Name

Philip Chabert (1737–1814): French scientist and veterinarian in Lyon. Latin: *ovis* = sheep;

esophagus = esophagus. English: Large-mouthed bowel worm.

Geographic Distribution/Epidemiology

Worldwide, mainly in sheep, goats, and rarely in cattle and wild ruminants. In sheep, prevalence rates of up to 90 % were reached.

Morphology/Life Cycle

The cylindric whitish worms reach as males a length of 12–16 mm and as females 20 mm. They are characterized by a large mouth capsule which is surrounded by numerous small cuticular teeth. The esophagus shows a typical constriction. The posterior end of the males is provided with a bursa copulatrix and two long spicula (Fig. 1). The females excrete nonembryonated eggs, which measure 70–100 µm × 40–60 µm. Depending on the temperature, the larva 1 hatches within 5–8 days and develops within 5–10 days into the sheathed infectious larva 3, which is swallowed by the next host or the same host (see Infectious larvae of nematodes). The sheath is disrupted before the larva 3 enters the mucous layer of the small intestine. Inside the wall, the larva 3 spends a histiotropic phase for a week and afterwards molts into the 4th larval stage, which leaves the wall and starts development via preadult stage (5th stage) into adults mostly in the ceca and colon. Larvae 4, preadults as well as adults suck blood. In stage 4, ► [hypobiosis](#) may occur (e.g., further development is stopped for a while).

Symptoms of Disease

The preadults and adults introduce lesions at the intestinal wall, bleedings and inflammations, which lead to diarrhea, bloody feces, loss of weight and of proteins, and to enteropathia.

***Chabertia ovina*, Fig. 1** Diagrammatic representations of the posterior ends of larvae of *Chabertia ovina* and related species. *B* bursa copulatrix, *C* mouth capsules, *E*

esophagus, *G* gubernaculum, *I* small intestine, *N* nerve ring, *S* spiculum, *T* leaf-like cuticular teeth surrounding the mouth

Diagnosis

Microscopical determination of eggs isolated from feces using concentration methods (e.g., ► [flotation](#); S.A.F.C.).

Incubation Period

Five to 7 days.

Prepatent Period

Seven weeks.

Infection

Oral uptake of larvae 3 within food. Larvae 3 may survive up to 10 months on the meadow.

Patency

Sixteen months, often only 2 months.

Prophylaxis

Rotation of pasture.

Therapy

Similar to that of Trichostrongylids.

Disease due to midsized, yellowish strongylid nematodes reaching a length of 12–20 mm (♀) and 11–6 mm (♂). They are characterized by an ovoid mouth capsule at the slightly bended anterior end. The mouth is provided with several small tooth-like cuticular protrusions and is situated at the anterior end of a small cervical bladder. Furthermore these worms possess there a ventral cervical farrow. The ovoid eggs are thin-shelled, contain only a few cells, and measure 72–100 × 38–63 µm when laid. *Chabertia ovina* is parasitic inside the cecum and colon of wild ruminants such as deers, etc., and in sheep and goats reaching there prevalence rates of 80–90 %. The following clinical symptoms may occur: loss of weight, slimy, and/or bloody diarrhea.

Chagas Disease: Nonepidemic Cases

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Although the Chagas disease seemed to have stopped its expansion in South and Central America due to insecticide spraying campaigns, recently (2013) a new spreading period has started. Thus, considerable prevalences have been noted, e.g., 1 % in Uruguay, 3–4 % in El Salvador and Honduras, 4–5 % in Argentina and Brazil, and more than 5 % in Bolivia and Ecuador.

Since millions of people from endangered regions have left their homelands and migrated to the USA, Europe, etc., cases of Chagas disease have become more common there compared to the few cases imported in former times by businessmen, social workers, or scientists. WHO (2010) estimates that 80,000–100,000 cases of Chagas disease have been imported at least into Europe – often still not yet detected due to hidden symptoms.

The Swiss authorities estimate that 2,000–4,000 persons out of the legally entered South Americans are carrying the Chagas trypanosomes. The calculated cases in Spain are still much higher, since health authorities calculate a prevalence rate of 2.3–3.8 % among the 1.2 million people coming from South and Central America reaching a total of 25,000–48,000 cases. These numbers are even low compared to those that are estimated by the Centers for Disease Control and Prevention (CDC) of the USA. According to recent data, about 500,000 of the immigrants should carry Chagas trypanosomes. However, also in other industrial countries like Germany, prevalence rates of 1.3–1.7 % (i.e., 1,000–1,450 persons) are estimated. All this will afford in future enormous costs in treatment and further health care, since ► [chemotherapy](#) of Chagas disease needs very long periods of treatment and is extremely costful.

Chagas, Carlos (1879–1934)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Brazilian physician, discoverer of the life cycle of ► *Trypanosoma cruzi*, which is the agent of the

so-called ► **American trypanosomiasis** or ► **Chagas'**; disease of humans and animals in South and Central America.

His full name was Carlos Justiano Ribeiro Chagas – son of a coffee farmer family. He got his M.D. in 1909 at the Medical School of Rio de Janeiro after submission of a thesis on hematological aspects of malaria. He worked from 1906 on for the rest of his life at the new Medical research institute in Rio de Janeiro, which was created by his friend Oswaldo Cruz (1872–1972), which exists still today and bears the name of its founder. During an antimalarial campaign close to Belem, Brazil, Chagas observed that so-called kissing bugs of the genus *Triatoma* contained flagellate protozoans which they transmit during their nightly sucking activity to humans and animals. As results of experimental transmissions of these flagellates to marmoset monkeys, he was able to prove the life cycle of this parasite that he named in the year 1909 at first *Trypanosoma cruzi* and still in the same year *Schizotrypanum cruzi*. This description of the new disease brought him international distinction thus being elected into the Brazilian National Academy of Medicine, receiving the at this time famous German Schaudinn Prize for Protozoology and Tropical Medicine and being two times proposed for the Nobel Prize (1913 and 1921) and by receiving in 1917

Chagas, Carlos (1879–1934), Fig. 1 Banknote of Brazil honoring Carlos Chagas

the directorship of the Oswaldo Cruz Institute at Rio de Janeiro (Fig. 1).

Furthermore, Chagas discovered the parasitic organism ► *Pneumocystis* in the lungs of his *Trypanosoma*-infected laboratory animals (guinea pigs), which is today one of the biggest threats for HIV-infected persons.

Pathology

► *Trypanosoma cruzi* infection occurs in Central and South America and is transmitted by triatomid ► bugs (► *Kissing Bugs*). These hematophagous ► *Hemiptera* evacuate their intestinal contents containing the infection's metacyclic forms, while feeding, in order to ingest more blood. Metacyclic forms enter either the skin through the site of the bite, are inoculated by scratching the itching bite wound, or penetrate the mucosa of the conjunctiva or mouth. ► *Amastigotes* multiply in adjacent muscle and fat cells in the dermis, producing an inflammatory ► *nodule*, the chagoma, which is composed of parasitized cells, histiocytes, and a periphery of neutrophilic granulocytes. This chagoma may persist for several weeks. Trypanosomes are disseminated via the lymphatics, often enlarging the regional lymph nodes. Hematogenous dissemination follows and amastigotes parasitize many tissues,

especially histiocytes, adipocytes, myocardial fibers, and autonomic ganglia in the gastrointestinal tract; this is accompanied by fever. The parasitized cells are usually destroyed (► *Pathology*, Fig. 13d). When the infection is transmitted by blood transfusion, it is particularly severe because it starts with the hematogenous phase of dissemination without any preceding immunization during the chagoma stage. However, the majority of patients with naturally acquired *T. cruzi* infection experience a benign or asymptomatic infection.

The most important lesions are in the heart, the esophagus, and the colon. The myocardium contains large ► *pseudocysts* of amastigotes without surrounding inflammation (Fig. 1). Destroyed myocardial cells are also found, with lymphocyte, plasma cell, and macrophage infiltration often forming "microabscesses" that later heal by fibrosis (► *Pathology*, Fig. 13d). During chronic Chagas' disease, which may last for years, the heart usually undergoes marked hypertrophy (400–800 g) and dilatation. Mural thrombi are commonly found. Next to the apex of the left ventricle, myocardial inflammation and fibrosis

Chagas' Disease, Man, Fig. 1 Giemsa-stained section through a muscle fiber with a pseudocyst of *Trypanosoma cruzi*

Chagas' Disease, Man, Fig. 2 TEM micrograph of a muscle fiber filled with *T. cruzi* stages

are often most advanced, and the ventricular wall may become so thin as to be transilluminable. After the Purkinje fibers are destroyed, conduction defects, such as arrhythmias, hypotension, tachycardia, right bundle branch block, and later bradycardia make their appearance. Myocardial failure responds poorly to digitalis and results in death, as does ventricular fibrillation. There are usually few amastigotes in the lesions of chronic Chagas' myocarditis, but the myocarditis with diffuse fibrosis still progresses. This has led to various hypotheses suggesting that delayed hypersensitivity or ► [autoimmunity](#) may participate in the pathogenesis. However, reviewing these, here is enough pathologic evidence to support a direct effect of *T. cruzi* on infected cells (Fig. 2).

The autonomic ganglia of the esophagus and colon may be destroyed either by parasitization or by an undetermined process. The destruction leads to an interruption of the peristaltic wave and dilatation of the viscus proximal to the destroyed ganglia, often resulting in megaesophagus and megacolon.

Chagas' ► [encephalitis](#) is seen especially in young children, with parasitization of neurons by amastigotes and destruction of even unparasitized cells. There is marked focal neuronal damage accompanied by lymphocytic infiltration and extending into the meninges. Death may occur after a disease course of only 1–2 months.

There are many cases known of spontaneous cure and of chronic asymptomatic parasitemia lasting for 20–40 years without apparent progressive organ lesions. Minor lesions include the lipochagoma resulting from the destruction of adipocytes by trypanosomes and a painful lipogranuloma which, if it occurs in the cheeks, interferes with eating.

Placental infection may occur and lead to ► [abortion](#). Sometimes the fetus becomes infected, resulting in encephalitis and death a few days or weeks after delivery.

Immune Responses

T. cruzi is able to infect virtually any nucleated cells of mammals. In infected mammals *T. cruzi* can be found either as flagellated trypomastigote or as amastigote replicating inside of cells. Amastigotes can be found both within phagocytic ► [vacuoles](#) as well as free in the ► [cytoplasm](#). After rupture of the host cell, amastigotes transform into ► [trypomastigotes](#), which are the most infective forms. The intracellular habit may be the reason why *T. cruzi* did not evolve mechanisms of adaptive genetic variation to alter expression of surface proteins such as occurring in African trypanosomes. In humans, the majority of infections with *T. cruzi* are thought to be asymptomatic. Chagas' disease typically represents a chronic disease, with a long-term interaction of the host's immune system and the parasite. Sterile immunity is seldom or never achieved and human *T. cruzi* infections are often dormant for decades. As in the case of *T. gondii*, reactivation has been described to occur during intentional immunosuppression for organ transplants or in ► [AIDS](#) patients. Mouse models of *T. cruzi* infection have been used by many investigators to study both acute and ► [chronic infections](#) to elucidate immune-response mechanisms leading to the control of the parasite or to autoimmune pathology. Differences in *T. cruzi* strains can greatly influence the immunological characteristics and disease outcome. In addition, inbred mouse strains have been classified as being susceptible or resistant to *T. cruzi* infection, but this

responsiveness clearly depends on the parasite strain as well.

A typical feature of *T. cruzi* infections in mice is a profound suppression in multiple components of the immune system, which, for example, can result in exacerbated viral infections (e.g., murine leukemia virus). Likewise, virtually all immune-defense mechanisms appear to be involved in the control of *T. cruzi* infection and disease development.

Innate Immunity

T. cruzi activates cells of the innate immune system by glycosylphosphatidylinositol and the Tc52-released protein as TLR2 agonists, glycoinositolphospholipid-containing ceramide as TLR4 agonist, and unmethylated CpG motifs as potential TLR9 agonists. TLR2-deficient mice develop enhanced parasitemia and mice deficient for the TLR adaptor protein myeloid differentiation factor 88 (MyD88) display impaired production of pro-inflammatory cytokines and enhanced susceptibility. During the very early phase of infection, NK cells are activated via IL-12 produced by macrophages in response to live, infective trypomastigotes. IFN- γ , produced very early by activated NK cells, has a protective effect on experimental *T. cruzi* infection in vivo. Both neutralization of IFN- γ and depletion of NK cells by mAb treatment rendered relative resistant mice more susceptible to the infection and increased parasitemia. However, IFN- γ produced in the later phases of acute infection may not be relevant for protection.

As the acute infection progresses, polyclonal activation of essentially all peripheral lymphoid cell types is induced. One minor subset intensely expanded is the $\gamma\delta$ T cells. Although the relevance of this subset for host protection is still uncertain, one study showed that $\gamma\delta$ T cells are able to modulate the intensity of parasitemia, mortality, and tissue inflammation.

B Cells and Antibodies

Polyclonal activation of B cells during the acute phase of infection leads to marked Ig production of all isotypes, but only a minor component of the Igs appears to be parasite specific. However,

transfer of serum containing *T. cruzi*-specific antibodies mediated significant protection against the infection. In this regard, *T. cruzi* differs from other intracellular pathogens, in that humoral responses do play a protective role against circulating trypomastigotes. CD5⁺ B1 cells may play an important regulatory role by their capacity to produce IL-10. It has been reported that mice carrying the xid defect and therefore lacking B1 cells showed an increased IFN- γ production and were more resistant than the appropriate control mice.

T Cells

A number of studies demonstrated that both CD4⁺ and CD8⁺ T cells were needed for parasitemia control and survival in acute infection. Elimination of CD4⁺ T cells by antibody treatment or in MHC class II-deficient mice resulted in markedly increased susceptibility to *T. cruzi* infection, while athymic mice receiving syngeneic CD4⁺ T cells were better able to contain parasitemia. The need for CD4⁺ T cells has been attributed to the production of cytokines stimulating macrophages to kill intracellular parasites and/or to help in the production of protective parasite-lytic antibodies. Elimination of CD8⁺ T cells by preventing MHC class I expression in gene-deficient mice or by treatment with mAb also resulted in markedly increased susceptibility to *T. cruzi* infection. Mice made deficient in both CD4⁺ and CD8⁺ T cells are even more susceptible to increased parasitemia and death, which is consistent with a crucial role for IFN- γ produced by both CD4⁺ and CD8⁺ T cells.

In contrast to other experimental parasitic infections, infection with *T. cruzi* does not result in a clear polarization of Th1 or Th2 cytokine responses, as both IFN- γ and IL-10 were found to be produced simultaneously. Instead, separate Th1 and Th2 waves may occur at different stages of infection within the same resistant host and a higher amplitude and more rapid onset of a Th1-type response correlated with resistance.

At least in the Brazilian strain model of infection, most of the IFN- γ appears to be produced from a very unusual subset of ab TCR⁺, NK1.1⁻, CD4⁻, and CD8⁻ (DN) T cells. However, for reasons unclear so far this cell population does

not seem to play any major protective or inflammatory role in *T. cruzi* infection.

Immunosuppression

The observation that effector mechanisms were impaired in mice infected with *T. cruzi* led to the search for soluble mediators of this deficiency. TGF- β , which exerts suppressive effects on macrophages and T cells, was found to be released in a biologically active, processed form by cultured spleen cells from *T. cruzi*-infected mice already on day 8 postinfection. Since in most cases TGF- β is produced in an inactive latent form, it was analyzed how activation occurs in *T. cruzi* infection. Recent findings suggest that *T. cruzi* trypomastigotes themselves have a potent enzyme capable of activating TGF- β . Since administration of recombinant TGF- β to resistant B6D2 F1 mice significantly increased both ► [morbidity](#) and mortality in these animals, TGF- β induced and activated by *T. cruzi* may represent a novel mechanism for pathogenesis.

Another candidate for a mediator of macrophage inhibition is IL-10. Like the "host protective" IL-12, IL-10 can also be produced by macrophages in response to live infective trypomastigotes. Since in vitro IL-10 is able to inhibit the ability of macrophages to kill intracellular *T. cruzi*, it has been considered as a "parasite protective" cytokine. In line with this, administration of neutralizing anti-IL-10 mAb could block the development of acute disease in susceptible C57BL/6 mice. In addition, it has been established that infections with *T. cruzi* (strains CL or Tulahuen) trigger a significantly stronger IL-10 production in susceptible than in resistant mice. On the other hand, IL-10 may also possess protective effects, since IL-10 knockout mice infected with the Tulahuen strain showed accelerated mortality, as compared to wild-type mice despite a reduced parasite load. In these IL-10-deficient mice, not only rIL-10 but also anti-IL-12 mAb reversed the susceptibility, leading to the conclusion that IL-10 may prevent toxic immune responses characterized by overproduction of IL-12 and IFN- γ . However, Treg cells as a

potential source of IL-10 and TGF- β do not appear to play a major role in regulating CD8⁺ T-cell effector responses during the acute phase of infection, nor in the muscle of mice during chronic *T. cruzi* infection. A second mechanism of immunosuppression beside soluble mediators involves the induction of activation-induced programmed cell death, ► [apoptosis](#). Selective triggering of CD4⁺ T-cell apoptosis has been described in experimental *T. cruzi* infection, which is mediated via the TCR-CD3 pathway and not via CD69 or Ly-6.

Autoimmunity

There is strong evidence that much of the pathology of chronic Chagas' disease, such as cardiac manifestations or peripheral neuropathy, is caused by autoimmune mechanisms. One antigen of *T. cruzi* (FL-160) has been implicated in molecular mimicry of nervous tissues. About 40 % of persons with chronic *T. cruzi* infections had antibodies to the FL-160 antigen, and antibodies to two epitopes in this protein have been shown to bind to human sciatic nerve. Ribosomal P proteins of *T. cruzi* are also able to trigger antibody responses against host P proteins, which, interestingly, have previously been implicated as autoimmune targets in SLE patients. Furthermore, human T cells and antibodies reacting with ► [myosin](#) and most likely involved in the pathogenesis of Chagas' cardiomyopathy may be triggered by a cross-reactive antigen of *T. cruzi*, which was identified recently.

Vaccination

The approximately 12–20 million individuals in Central and South America infected with *T. cruzi* represent an important medico-social problem. Various chemotherapeutic drugs have become available but no vaccines have been developed. An important effort of Public Health Organization in Brazil, Uruguay, and Argentina has successfully controlled the domestic hemiptera vector ► [Triatoma infestans](#), and transmission of

Chagas' disease in these countries is practically reduced to blood transfusion accidents. In other South and Central American countries, anti-vector campaigns are successfully in progress. This success in transmission control considerably decreases the interest in vaccination against Chagas' disease. However, a large number of animal species from different orders of mammals are *T. cruzi* reservoirs in nature, including domestic animals like cats and dogs, which represent potential sources of infection for man. Thus, if available, vaccination would have a double interest: (1) control of animal's sources of infection and (2) protection of humans migrating in new eventual endemic areas will be possible in the future in the Amazon region. No evidence of ► [antigenic variation](#) has been found in *T. cruzi* as described for the African trypanosomes. However, two main lineages of parasites have been recently identified by molecular markers, one more frequent in human infections and the other in ► [animal reservoirs](#). In both lineages, the parasite from the vector insect stage (Triatominae) can be grown easily in liquid culture with semisynthetic or defined medium, while the vertebrate form can also easily grow in tissue culture using a variety of cells from mammals or birds. Thus, the preconditions for developing vaccines directly from parasites' materials are there, either for development of attenuated lines or chemical purification of antigen components.

About 90 % of infected persons recover from the acute stage, but continue to have low parasitemias for an indefinite period of time without clinical signs. A small proportion of them later develop the chronic form of Chagas' disease, with chronic myocarditis or megaesophagus or megacolon syndromes. In the asymptomatic period, carriers have antibodies to *T. cruzi*, and this immune response has been considered responsible for resistance to challenge infections in experimental models and man.

Attempts have been made to develop live vaccines using parasites attenuated by chemical modification, by culture passage, and by X-ray irradiation. Most of these live vaccines have

induced partial immunity but have also shown pathogenic side effects. Some authors have reported protection of laboratory animals immunized with subcellular fractions of *T. cruzi*. Others have described a 90-kDa glycoprotein which exists on the parasite's cell surface throughout the life cycle and which was partially protective in mice and in marmosets. An important objection to the use of natural sources of antigens from *T. cruzi* for vaccination is the description by different authors of molecular mimicry between *T. cruzi* antigens and different cell proteins from the human host with description of parasite-antigen driven human T-cell clones that react with cardiac myosin. Antibodies to ribosomal P proteins of *T. cruzi* have been shown to lead to cross-reaction with heart tissue and eventually be implicated in the induction of myocarditis. Because of these potential cross-reactions and consequent autoimmune pathologies, some authors consider that the development of a classical vaccination against Chagas' disease is not suitable. There are apparently two types of antibodies with different functional activities. Protective or complement-dependent "lytic" antibodies (LA) are associated with host resistance, whereas "conventional" ► [serology](#) antibodies (CSA) are not. Chronically infected patients or animals have both LAs and CSAs, whereas experimentally immunized animals only have CSAs. However, it is not yet possible to decide whether a vaccine induces protection without knowing first if some of its components will not provoke autoimmune pathology with later manifestations as in natural infection.

Different groups have recently shown that CD8⁺ T cells, IFN- γ , and macrophages play an essential role in the control of parasite multiplication in the acute phase. They have identified cytotoxic epitope in the trypanosome surface antigen 1 (TSA-1) and in trypanosome surface proteins members of the trans-sialidase superfamily. Effective protection against the acute infection was obtained with immunization by plasmid DNA containing genes corresponding to these antigens.

For short survey see ► [Trypanosoma cruzi](#).

Chagom

Initial sign (swelling of skin) of Chagas' disease.

Chalimus

Larval stage of ectoparasitic copepods (► *Lepeophtheirus salmonis*, Lernaecera).

Chancr

Papular and later ulcerating lesion caused by African trypanosomes which are present extracellularly in the subcutaneous tissue at the site of the bite of the Tsetse fly (► *Sleeping Sickness*).

Chandlerella

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of filarial worms (family Onchocercidae) of birds. The adults live in the connective tissues around blood vessels, where the more than 200 µm long sheathed microfilariae parasitize, and they are ingested by their vectors (► *Ceratopogonids* = midges). See Filarial worms of animals.

Cheilospirura hamulosa

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species (syn. *Acuaria cheilospirura*) is a nematode that parasitizes in India and worldwide in other warm countries in the ventriculus (gizzard) of fowls or chickens and other birds. Although clinical signs are lowgraded, lesions inside the intestinal tract are severe and lead to loss of weight and reduced egg production. The

life cycle runs indirectly, since grasshoppers, beetles, and weevils are involved as intermediate hosts.

Therapy

See Nematocidal drugs.

Cheiracanthus siamensis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Old name (1889) for ► *Gnathostoma spinigerum*.

Chelae

Sharp claws at the tips of chelicerae of mites (e.g., ► *Cheyletiella*) or spiders.

Chelicerae

The first pair of appendages of ► ticks and other arachnids; they consist of three segments starting from the very end of the ► *basis capituli*. In ticks they become essentially modified and are used for grasping, piercing, cutting, etc. during food gathering or feeding.

Chelicerata

Synonyms

Amandibulata

Classification

Subphylum of ► *Arthropods*. Arthropods that lack antennae and mandibles are commonly placed in the subphylum Chelicerata, thus named because the first anterior appendages become feeding organs called ► *chelicerae* (► *Arthropoda/System*). The Chelicerata contain as parasitic group the economically and medically important order of ► *Acarina* (► *Ticks* and ► *Mites*), while the sister groups of ► *scorpions* and ► *spiders* may have a considerable medical impact as poisonous animals.

Chemical Disinfectants

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Cyst stages of protozoans and worm eggs are commonly very resistant against chemical disinfections. Thus, each product has to be tested individually on its efficacy. The paper of Dauschies et al. (2013) gives an overview on effective and noneffective compounds/products.

References

Chemokines

► **Cytokines** that are involved in infectious diseases (e.g., like IL-9) being responsible for the induction and migration of subsets of leukocytes. This is a superfamily of low molecular weight (6–17 kDa) cytokines, which recruit distinct groups of leukocytes and activate them through increased adhesion, degranulation, and respiratory burst. Up to now 44 different chemokines are described plus 21 chemokine receptors. The chemokines represent excreted proteins consisting of 67–127 amino acids. Previously chemokines were grouped into inflammatory or homeostatic chemokines. Today however, it is shown, that at least some have double functions.

Chemoprophylaxis

Administering a chemical agent to avoid the development or spread of a certain disease (► **Chemotherapy**).

Chemotaxis

Movements of protozoans/cells due to attraction by chemical gradients; from Greek: *taxis* = position.

Chemotherapy

Wolfgang Raether¹ and Achim Harder²

¹Hoechst, Frankfurt, Germany

²Bayer HealthCare AG, Division Animal Health, Leverkusen, Germany

Definition

Drug application after appearance of clinical signs may eliminate or damage pathogens/parasite and lead to recovery of health in the patient.

General Information

Chemotherapy (CT) and ► **chemoprophylaxis** (CP) are experimental sciences dealing with drugs that selectively inhibit or destroy parasites or other pathogens. Thus, attention to selective toxicity of antiparasitic drugs is central to CP and CT, and useful chemotherapeutic agents should affect the parasite more adversely than the host. Until now, there is no completely safe drug. Knowledge of sources of drugs (pharmacognosy), action and fate in the body (pharmacodynamics), use in the treatment of disease (therapeutics), adverse effects (toxicology), and contraindications is a must to evaluate potential risks as well as possible benefits of drugs to the patient's well-being.

Withdrawal Time of Drugs in Target Animals

Claims made by the drug manufacturer for a drug product in treatment of target animals consumed by humans (poultry, bovines, equines) must have been investigated and evaluated in the target animal, besides toxicological studies in rodents (rat, mouse) and other species. The latter are required to determine the ADI. The acceptable daily intake is the dose of a drug residue in edible tissues, like meat, various organs, fat, etc., that during the entire lifetime of a person seems to be without obvious risk to health on the basis of all toxicological data known at the time. The ADI for humans may be determined by applying a safety factor of 1:100, or a safety factor of at least 1:1,000 in case of a teratogenic drug. Therapeutic claims made by the manufacturer must coincide with safety and tissue residue data for the drug approved by government regulatory agencies. The **preslaughter withdrawal time** refers to the interval from the time an animal is removed from medication until the permitted time of slaughter (► **Nematocidal Drugs, Animals**, Table 2). During this interval the residue of toxicological concern will reach a safe concentration as defined by the maximum residue limit (MRL). Recent workshops give guidance to the analytical approaches.

There may be three **types of tolerances** in defining allowable concentrations of drug residues at the time of slaughter up to the time of consumption by humans. (1) The finite tolerance (measurable amount of drug residue permitted in food), (2) the negligible tolerance (insignificant amounts of residue, i.e., a small fraction of maximum ADI), or (3) the zero tolerance (no residue is permitted in feed or food because of extreme toxicity or because the drug is carcinogenic). Questions and answers concerning specific legislation of the establishment of MRLs in the European Union cf. website address <http://www.emea.eu.int/htms/vet/>.

Drugs

General Information

Drug can be broadly defined as any chemical compound that affects living processes and is used in the diagnosis, prevention, treatment (cure) of disease(s), or for controlling or improving any physiological or pathological disorder or for relief of pain in animals and humans. A drug may have various names: one or more **chemical names** depending on rules of chemical nomenclature used: (1) usually one international nonproprietary name (**INN**), (2) one or more nonproprietary names, e.g., in different countries, and (3) usually several proprietary names or brand names of a drug product. Drug products are galenic, pharmaceutical, and/or medicinal preparations of drugs, e.g., various drug forms and dosage forms. These may be powders, tablets, pills, capsules, sustained-release boli, or several liquid preparations, e.g., mixtures, or emulsions for oral administration or medicated feed articles. Dosage forms for injections are ampules, multidose vials, large-volume capped bottles, and implants that may be hard, sterile pellets inserted under skin. The parenteral administration of such preparations may be done either by subcutaneous (s.c.), intramuscular (i.m.), intravenous (i.v.), intraperitoneal (i.p.), or intrathecal (i.e., into the subarachnoid space) injection. For application to skin surface several external preparations of drugs may be used such as liniments, lotions,

ointments, creams, dusting powders, or aerosols, e.g., topical insecticides.

Critical Use of Drugs in Concert with Other Control Measures

The administration of chemotherapeutic or chemoprophylactic agents can only be regarded as a suitable measure when individual cases or parts of the population or herds are treated under controlled conditions after a diagnosis has been made. Parasitism in the field is often a multifactorial problem. Thus, methods of control must include epizootiological/epidemiological and therefore ecological and economic aspects as well as consideration of the development of resistance to drugs by the parasites. Drug application is important but not the only control measure in a large-scale, complex **control strategy**. The aim of each of the measures that can be taken is to reduce or even completely eliminate the parasite population in its environment. However, the tasks, solutions, and objectives of a certain strategy require profound knowledge of the biology of the parasites and the ► **epizootiology** or ► **epidemiology** of parasitism. Thus, when planning and implementing programs of this type, account must be taken of the many different interactions between host and parasite on the one hand (mode of transmission and susceptibility of the population) and those between parasite and/or host and biotype on the other (e.g., pathogen reservoir). Knowledge of the **environmental factors** such as temperature, humidity, soil structure, and prevailing weather conditions, which are critical within the infection chain, are of practical importance for forecasting parasitic risk in certain areas.

In order for the chemotherapeutic agent administered to have its optimum effect against the parasites, the **time of treatment** must be adapted to the development cycle of the parasite. An example of this is the ► **metaphylaxis** often practiced in veterinary medicine when the aim is to prevent the outbreak of disease in animals already infected, i.e., to kill off certain parasitic developmental stages in the host before serious damage occurs. The correct timing of the treatment in relation to the course of the infection is therefore critical for the success or failure of drug ► **metaphylaxis**.

As is well known, the acquired and often species- specific or even life-cycle-stage-specific **immunity** (“► [Immune Responses](#)”) of the host plays an important role in the elimination of parasites. It would be ideal if CT and immunoprophylaxis (“► [Vaccination](#)”) had a synergistic effect. However, drugs can suppress the development of immunity and the immune response of the host may not materialize. Thus, the lack of an immune response may result from starting treatment at the incorrect time in relation to the course of the infection. This may be true for instance when treatment and infection take place at the same time, or the treatment starts shortly after the infection, as a result of which the parasites are immediately eliminated (without antigenic effect).

In modern livestock farming in which large numbers of animals are reared and fattened in a confined space, continuous drug application must often be performed via the feed. This is because other preventive measures, such as methods for maintaining good ► [hygiene](#) and disinfection (“Disease Control”), have either not yet been developed or are as yet inadequate (such as reliable immunoprophylaxis or vaccination) against the high risk of parasitism that exists with this form of farming. Thus, without prophylactic medication, the rapidly increasing pressure of infection would lead to an outbreak of disease in a herd. Consequently, in the fattening of poultry feed additives such as ► [coccidiocidal drugs](#) can control outbreaks of coccidiosis and therefore serious financial losses can be reduced to a minimum during the fattening period.

A few examples clearly show that prophylactic or therapeutic agents must not be used in a stereotyped fashion. Often their use must be adapted to varying relationships between the parasite and host populations and their environment; only then will a treatment campaign have the desired success. Flexible handling of the chemotherapeutics also considerably slows down the development and therefore the spread of drug-resistant parasites. Before the start of every course of treatment adverse effects of the chemotherapeutic agent must be taken into account in the treatment plan. They should be reduced to a minimum by varying the dosage regimen and the treatment intervals. Anaphylactic reaction to the drug used or the intrinsic toxicity of

the drug including its toxic metabolites may induce a severe and life-threatening risk to a patient. This may be applied also to severe allergic reactions caused through toxic metabolic products of endoparasites released after the drug has killed parasites.

Cheyletiella parasitivorax

- [Mites](#) of rabbits.

Cheyletiella Species

Species of the genus *Cheyletiella* reach a size of 0.2–0.5 mm parasitizing the hair of dogs (*C. yasguri*) and of foxes, cats (*C. blakei*), occasionally specimens are found even on humans. They are characterized by strong claws at the pedipalps (Fig. 1). The eggs (Fig. 2) are attached by filaments to hair. The total development (including egg – 1 larva – 2 nymphs) until adult males and females takes 3 weeks. Due to their feeding activity at the skin, infestations with such mites lead to a strong itching, to dermatitis, to loss of hair, allergic reactions, and bacterial superinfections. Often such small mites are

covered by skin detritus, thus were not clearly seen and therefore called “walking dandruff.”

and eventually to death due to the lack of oxygen.

► [Ciliophora](#).

Chilodonella Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *cheilos* = lip; *ontos* = tooth. English: skin dimmer.

There are described three species of this genus (*Chilodonella cyprini*, *C. uncinata*, and *C. hexasticha*), which parasitize at the skin of a broad spectrum of fresh water fish including carps (Figs. 1 and 2). These ciliates measure about $80 \times 40 \mu\text{m}$, have a characteristic heart-like shape, and possess a different upper- and under-side with respect to the formation of their rows of cilia. As other ciliates, these parasites possess two

Chilodonella Species, Fig. 1 Light micrograph of a *Chilodonella* specimen

differently shaped nuclei (an ovoid macronucleus and a tiny micronucleus) and two pulsatory vacuoles. Characteristic is a ventral invagination leading to a “cell mouth” = cytopharynx. Reproduction occurs by a cross binary fission giving rise to new ciliates, while sexual processes (with exchange of genetic material) between two organisms take place during the process called ► [conjugation](#). Under bad environmental conditions these ciliates may excrete a cyst wall, within which they may overcome these conditions and survive for long at the bottom of aquaria or ponds.

Transmission

The free swimming ciliates seek fish and attach at their surface.

Symptoms of Disease

Typical symptoms are that the infested surfaces of fish are bleached and appear with dimmed-whitish regions (Fig. 3), which may reach a size of one third of the body of small fish. In case of infections of the gills, the fish have problems with breathing and start to rub their gill covers at stones. In case of mass infections fish may die (e.g., in densely filled carp ponds).

Diagnosis

Microscopical investigations of fresh unstained smear preparations of gill surface material.

Prophylaxis

Take out visibly infected fish from aquaria or ponds in order to slow down propagation of parasite load.

Treatment

In aquaria, treatment can be done by Ciliol[®] of Fa. Sera, Germany.

Chilomastix mesnili

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *cheilos* = lip; Latin: *mastax* = chewing system.

Systematical Position

► [Diplomonadida](#), ► [Retortamonadida](#).

This species is an apathogenic unicellular flagellate living inside the colon and cecum of humans. The trophozoite measures 6–24 μm in length and possess three anterior flagella and a short laterally recurrent flagellum, which runs inside a folding of the cell body. They do not possess an ► [axostyle](#), which is common, e.g., in trichomonads like ► [Trichomonas vaginalis](#) (Fig. 1). Besides these flagellated stages occur spherical stages with retracted flagella.

Chitin

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Chitin is a polysaccharide of *N*-acetylglucosamine (GlcNAc) residues joined by $\beta(1 \rightarrow 4)$ glycosidic links that forms the cell walls of fungi, the exoskeletons of ► [arthropods](#), and special structures of mollusks, cephalopods, and even some fish species. In endoparasites, this polymer is a component of the nematode eggshell, the protective sheath of microfilariae, and the cyst walls of ► [protozoa](#), but is also expressed at the cell surface of trichomonad species. Chitin is synthesized by the stepwise polymerization of GlcNAc from UDP-GlcNAc as catalyzed by chitin synthase. The straight chains of the chitin polymer are important for the maintenance of the structural integrity and protection of the organism from environmental, chemical, and mechanical

damages. As chitin synthesis and assembly do not occur in higher animals, these processes serve as targets for antiparasite chemotherapy.

Chitin Synthesis Inhibitors

Products that hinder molt of insect larvae (they are used e.g., to interrupt larval development of fleas).

Chloroquine New Treatment Regimens

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The use and efficacy of the old first-line antimalarial compound was based on nanomolar levels of the drug inside a treated person. This led to the development of the well-known recent resistances in many regions of the world. However, some research groups showed when patients used chloroquine in a way that offers micromolar levels that this way led to other pathways of efficacy. The results of an increased efficacy, but also the treatment risks, are summarized in the review of Ch'ng et al. (2012).

Cholangiocarcinoma

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Asian liver flukes (e.g., ► *Opisthorchis viverrini*, ► *Clonorchis sinensis*) cause severe health problems in Southeast Asia leading to extremely high cancer rates in the population especially when compared to Europe or the USA. Clinically, liver cancer rates are divided into two common ones. Most common are the hepatocellular carcinomas (HCC) and cholangiocarcinomas (CAA), while the less common subtypes occur in rates of less than one case per 100,000 people (Sithithaworn et al. 2012). Since especially the cholangiocarcinoma rates are extremely high in Northeast Thailand and Korea (reaching 60 cases, respectively 12 cases per 100,000 inhabitants), the important deleterious effects of liver fluke infections are obvious.

Cholera

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *kholera*; English: *drip* = flow of bile;
Hebrew: *chaul rah* = bad disease.

Cholera, Fig. 1 Photo taken from cholera cultures at occasions of Koch's expedition to Cairo (1883)

This disease due to the gram-negative bacterium *Vibrio cholerae* ($0.5\ \mu\text{m} \times 1.5\text{--}3\ \mu\text{m}$) has main symptoms such as watery diarrhea, vomiting, and severe dehydration, which may lead to death (due to shock reaction) or may stay on the level of common, not life-threatening diarrheas. Therefore, it is needed to initiate differential examinations, if infections with parasites (e.g., ► *Entamoeba histolytica*, ► *Cyclospora*, or ► *Isospora*) are supposed. Among the 200 serotypes of *Vibrio cholera*, which possess the main surface antigen O, only two (O1 and O139) lead to the endemic and epidemic cholera. The recent seventh cholera pandemic is different from the preceding ones by the fact that it is not based on the classic *Vibrio* but on the biotype El Tor (named according to the quarantine station on the Sinai peninsula, where this type was isolated first in 1905).

Cholera, Fig. 2 Light micrograph of cholera vibrios taken from a smear preparation of Koch's time

History

Robert Koch was the first to cultivate and to describe this bacterium on his expedition to Cairo, Egypt (1883) (Figs. 1 and 2). How dangerous this expedition was is shown by the deadly infection of the French scientist Louis Thullier from the Pasteur Institute in Paris at the same time in Cairo.

Cholesterol

This protein, which is an essential component of host cell membranes was recently shown to be necessary for binding and internalization of *Leishmania* stages and the subsequent presentation of leishmanial antigens in infected macrophages. Cyclodextrin-based compounds modulate cholesterol levels.

Chorioptes bovis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Mange mite of cattle (Fig. 1). All stages feed by eating skin particles thus inducing allergic skin reactions, mainly due to their excretions. Males reach a size of $300\text{--}450\ \mu\text{m}$, females grow up to $600\ \mu\text{m}$. The complete development needs about 3 weeks on their host. They may survive away

Chorioptes bovis, Fig. 1 *Chorioptes bovis* from ventral. EI egg, H attachment system, PT pretarsus

from their host for up to 70 days. Since they occur mostly close to the claws, the disease is called “foot-mange,” which, however, has mostly not very severe symptoms.

Chorioptes Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The following *Chorioptes* species had been described from a variety of hosts belonging to different groups (Table 1).

Chorioptes Species, Table 1

Chorioptes species	Host family	Host species
Chorioptes bovis	Bovidae, Cervidae, Camelidae, Equidae	Bos taurus, Bison bonasus, Bubalus bubalis, Taurotragus oryx, Tragelaphus angasii, Capricornius crispus, Ovis aries, Ovis dalli, Capra hircus, Rupicapra rupicapra, Ammotragus leroia, Gazella gazellus, Capreolus capreolus, Lama lama, Camelus bactrianus, Equus asinus, Equus burchelli
Chorioptes crewei	Bovidae	Cephalophus rufilatus
Chorioptes mydaus	Methitidae	Mydaus javanensis
Chorioptes panda	Ursidae	Ailuropoda melanoleuca, Ursus thibetanus, Ursus americanus
Chorioptes sweatnani	Cervidae	Alces alces
Chorioptes texanus	Bovidae, Cervidae	Capra hircus, Capricornis swinhoei, Bos taurus, Dama dama, Alces alces, Rangifer tarandus

Chromidial Bodies

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *chroma* = color; *oideos* = similar.
Structures (e.g., in amoebae) consisting of
ribonucleic proteins, which can be determined
by coloration with basic dyes.

Chromosomal Diminuation

In the nematode of the horse (► *Parascaris
equorum*) and in some other ► *nematodes* the
large compound chromosome is divided into
small portions during divisions of somatic cells,

which then have different quantities of DNA,
while this does not happen during formation of
gametes.

Chromosomes

Protozoa

In many protozoans the correct number of chromo-
somes is unknown due to the fact that the nuclei are
very small and/or the chromosomes do not con-
dense during the ► *nuclear division* (e.g., in
► *Coccidia*). The ploidy of the different parasitic
protozoans is also only poorly understood.
DNA-measurements of all life-cycle stages showed
that the coccidian genera ► *Eimeria*, ► *Sarcocystis*,
► *Plasmodium*, ► *Theileria*, ► *Babesia*, and sev-
eral genera of the hypermastigotes
(► *Barbulanympha*, Gametes/Fig. 8) are haploid
(except for the ► *zygote*), while the trypanosomatid
genera ► *Trypanosoma* and ► *Leishmania* are dip-
loid (except for a few haploid stages in the vector).
This diploidy is, however, probably only found in

^aSmaller than 150–200 Kb^b350–900 Kb^cBigger than 1 Mb^dThe Australian isolates possess a further medium sized chromosome^eRecent result of Willhoeft and Tannich using pulsed field gel electrophoresis indicate the existence of 31–35 chromosomes ranging from 0.3 to 2.2 Mb, and a functional ploidy; the haploid genome size is thought to be around 20 Mb

the maxichromosomes (cf. Gametes/Fig. 7, ► *Trypanosoma*). In some groups (e.g., trypanosomatids) the size of the chromosomes varies completely within an individual; thus this polymorphism also poses problems in counting. The application of different methods (e.g., pulse field electrophoresis, counting of kinetochores in ultrathin sections, etc.), however, allow some conclusions to be drawn (Table 1). Indications for (sex)

determination of gametes are scarce and mostly lacking.

Metazoa

Fertile adult stages of most metazoan are diploid (=2n) apart from some digeneans and ► ticks, which may be either haploid (n) or

Chromosomes, Table 2 Chromosome numbers of some metazoan parasites

Number of chromosomes (2n)	Species	Stage	Systematic position

triploid (3n). ► **Sex determination** mostly occurs by formation of morphologically different sex chromosomes. These differences, however, are not very significant in some groups of parasites. Thus heterochromosomes could not be unequivocally identified in the

karyotypes of schistosomes, and only after the use of the so-called C-band treatment an univalent sex chromosome has been discovered in the female of several schistosome species. Table 2 summarizes the chromosome numbers of some selected species of metazoan parasites showing a rather large scale.

Chronic Infections

Long persistent infections mostly occurring in natural hosts and characterized by regular fluctuations in the level of parasitemia (e.g., ► *Plasmodium* sp., trypanosomiasis) or in the quantity of the parasitic load (e.g., filariae), ► *Arboviruses*.

Chrysomia bezziana

► *Diptera*. This fly the larvae of which are called Old World Screwworm initiates ► *Myiasis*, *Man*.

Chrysomya megacephala

Common blowfly, which in Asia is called Oriental latrine fly due to its feeding on filth material, animal carcasses, garbage, etc. The larvae may also cause myiasis in humans as well as act as mechanical vectors of viruses, bacteria, and parasites.

Chrysops Species

Genus of ► *Diptera*, belonging to the brachyceran family Tabanidae (e.g., *Chrysops caecutiens*, *C. relictus* in Europe). They are often beautifully coloured blood suckers (as females) of up to 1.5 cm in length and possess large, coloured

Chrysops Species, Fig. 1 Light micrograph of the dorsal side of *Chrysops* sp.

Chrysops Species, Fig. 2 Anterior front of *Chrysops* sp.

eyes (Figs. 1 and 2). Their sawing mouthparts cut wounds into the skin, which become filled by blood. Thus they are pool-feeders. Their bite is rather painful. They act as vectors of filariid

worms (e.g., ► *Loa loa*) or mechanical transmitters of viruses and bacteria.

Chyluria

Symptom in ► *lymphatic filariasis* due to *Wuchereria* or *Brugia* worms.

CIC

Circulating immune complexes (► *Immune Responses*).

Cilia

► Flagella.

Cilia (sing. Cilium) although shorter possess the same internal structures (► *Axoneme*) as ► *flagella*, but show different (often coordinated) movements due to interconnecting structures at their ► *basal bodies*.

Cimicidae, Cimicids

Reiner Pospischil

PMP-Biosolutions, Bergheim-Fliesteden,
Germany

Introduction

The species of Cimicidae have a uniform appearance, which differs only slightly from species to species. *Cimex lectularius* is therefore sometimes confused with other also bloodsucking species of Cimicidae (Usinger 1966). The temperate bed bug is replaced in the (sub)tropical Asia and Africa in many places by the tropical bed bug *Cimex hemipterus* that requires higher average temperatures than *C. lectularius*. *C. hemipterus* is rarely found outside the tropics and subtropics.

Cimicidae: Systematics

The Cimicidae belong to the order Heteroptera and are split into six subfamilies and 22 genera representing a total of 74 species (Table 1). Only two species live permanently as ectoparasites on humans, the temperate bed bug *Cimex lectularius* and the tropical bed bug *Cimex hemipterus*. The other species are predominantly host specific to certain mammals and birds (Goddard and DeShazo 2009; Usinger 1966).

Cimicidae: Distribution and Hosts

The subfamily Cimicinae includes the genera *Cimex* and *Oeciacus* with 31 species (Table 2). Most of these species are associated with bats, others (both *Oeciacus* species and *Cimex columbarius*) with birds, respectively. Two species (*Cimex lectularius* and *C. hemipterus*) infest a broad range of hosts (man, domestic and wild mammals, bats, and birds).

One species of the subfamily Cacodminae, *Leptocimex boueti*, infests Hominidae including *Homo sapiens*. All other species live on bats and

Cimicidae, Cimicids, Table 1 Classification of the Cimicidae

Subfamilies (6)	Genera (22)	Species (74)

Subfamilies	Hosts
Primicimicinae	Bats (Molossidae and Vespertilionidae)
Cimicinae	Bats (Molossidae and Vespertilionidae)
Cacodminae	Bats (Emballonuridae, Molossidae, and Vespertilionidae) Flying foxes (Pteropodidae) Hominidae
Afrocimicinae	Flying foxes (Pteropodidae)
Latrocimicinae	Bats (Noctilionidae)
Haematosiphoninae	Birds (Apodidae, Cathartidae, Furnariidae, Hirundinidae, Phasianidae, Psittacidae, Strigidae, and Tytonidae)

flying foxes. The subfamily Haematosiphoninae is associated to birds (Usinger 1966).

Most species live in the tropical and subtropical areas (22 in Africa, 10 in South America, and 16 species in Southeast Asia). One species is restricted to Australia, 14 species to the south of North America, and five species to Central Asia. Two species (*Cimex lectularius* and *C. hemipterus*) occur worldwide (Usinger 1966).

Only five cimicid species are prevalent originally in Europe (Table 3). Two species are regularly found in Europe on birds, the swallow bug *Oeciacus hirundinis* and the pigeon bug *Cimex columbarius*. These types penetrate occasionally from nests that are located on walls or in attics or in apartments when the birds have left the nest in late summer. But they use humans only

^aCosmopolitan species

occasionally for a short time as a host. *C. pipistrelli*, *C. dissimilis*, and *C. stadleri* occur on bats (Wachmann et al. 2006).

***Cimex lectularius*: Common Bed Bug**

The adults of *Cimex lectularius* are approximately oval 4–6 mm in length and reach up to 9 mm because the segments of the abdomen are spread apart telescopically during the blood meal. The nymphs and adults are strongly dorsoventrally flattened, light to medium brown colored, and covered with short hairs. After blood feeding, the bugs are dark colored and nearly round in diameter. The nymphs go through five stages and are similar in shape to the adults. However, they are light brown colored. The proboscis is folded under the head and the thorax in resting position. It consists of two lancets which are formed by the maxillae and mandibles, which together form a double pipe through which the anticoagulant saliva is injected into the injection site, and on the other hand, the blood can be absorbed. The labium surrounds the pipe as

protection. The proboscis is folded forward for injection of the skin and the uptake of blood and the labium serves now as a guide during penetration. The oval eggs are whitish, sometimes yellowish to pink color, about 1 mm long and 0.5 mm in diameter (Boase 2007; Reinhardt and Siva-Jothy 2007; Usinger 1966).

During the day, bed bugs rest in the tight cracks and crevices (especially in the bed frame and the seams of mattresses, but also behind rub rails and picture frames, in light switches, in corrugated cardboard, in furniture, and under carpets). Bed bugs often infest bedrooms, but they can also be found in other rooms depending on the behavior of people.

Cimex lectularius is mainly spread passively through used furniture and furnishings, appliances, and transport cages for poultry, with vehicles or luggage. An active migration of bed bugs from infested rooms is slow and only possible over short distances (Boase 2007).

***Cimex lectularius*: Medical Importance**

Transmission of diseases by bed bugs has not yet been observed; however, the potential of bed bugs to act as disease vectors is unclear. Forty human pathogens were detected in *Cimex lectularius* (Goddard and DeShazo 2009; Table 4). However, a transmission to humans during the blood meal was not found until now (Boase 2007; Goddard and DeShazo 2009; Harlan et al. 2008). Most references that were included in the reviews of Burton (1963) and Goddard and DeShazo (2009) date from the first half of the twentieth century. Since the renewed increase in bed bug populations about 15 years ago, bed bugs are again increasingly examined in terms of their power to transmit pathogens to humans.

The transferability of the hepatitis B virus has been studied by several authors. The virus can be detected up to 35 days after intake with a blood meal and is passed through a molting step to the next stage (Blow et al. 2001; Jupp et al. 1991). Theoretically, a transmission would be possible if bugs are crushed during the blood meal and blood from the bug enters a wound. The transmission of

Cimicidae, Cimicids, Table 4 Human pathogens found in *Cimex lectularius* (Burton 1963; Goddard and deShazo 2009 – incl. further references)

Group	Human pathogen
Nematodes	<i>Wuchereria bancrofti</i> , <i>Mansonella ozzardi</i>
Protozoa	<i>Leishmania donovani</i> , <i>L. tropica</i> , <i>L. braziliensis</i>
Bacteria	<i>Bacillus anthracis</i> , <i>Borrelia duttoni</i> , <i>B. merionesi</i> , <i>B. recurrentis</i> , <i>Brucella abortus</i> , <i>B. melitensis</i> , <i>B. suis</i> , <i>Coxiella burnetii</i> , <i>Francisella tularensis</i> , <i>Leptospira icterohaemorrhagiae</i> , <i>Mycobacterium leprae</i> , <i>Rickettsia prowazekii</i> , <i>R. rickettsii</i> , <i>R. typhi</i> , <i>Salmonella paratyphi</i> , <i>Staphylococcus aureus</i>
Viruses	Hepatitis B virus (HBV), yellow fever virus, smallpox virus, lymphocytic choriomeningitis virus (LCMV), human immunodeficiency virus (HIV), polio virus

hepatitis B virus over the eggs to the next generation is not possible (Blow et al. 2001; Jupp et al. 1991; Silverman et al. 2001). A possible transmission of human immunodeficiency virus (HIV), which can be taken during the blood meal by the bugs, has been thoroughly investigated. Based on the available data, transmission of HIV by bed bugs is unlikely (Goddard and DeShazo 2009). Asthmatic reactions of people who are allergic to bed bug infestations were described by Abou Gamra et al. (1991) and WanZhen and KaiShong (1995).

***Cimex lectularius*: Reaction to Bites**

The injection of salivary proteins may induce sensitive sting reactions in people after the bed bug has completed its blood meal. A detailed overview of preferred infested parts of the body and of human responses to bed bug bites was given by Bauer-Dubau (2009), Goddard and DeShazo (2009) and Harlan et al. (2008).

The skin reactions which are caused by the saliva of the bugs are very different. Depending on the individual sensitivity, they may result in no

or only mild reactions to the bed bug bites or cause itchy wheals within the first 24 h after infection, which may persist for several days. However, it can also lead to several days of delayed reactions. In susceptible people, the bug infestations can cause extensive skin inflammation and disturbance of the general condition (Bauer-Dubau 2009; Fletcher et al. 2002; Sansom et al. 1992; Usinger 1966).

***Cimex lectularius*: Pheromones**

Bed bugs emit different compounds which serve as aggregation pheromones and alarm pheromones depending on their concentration. These compounds can be registered by bed bugs over a distance of up to 7 cm with receptors, which are localized on the terminal segment of the antennae.

The following active components were detected in aggregation pheromones of bed bugs: E-2-hexenal; E-2-hexenol; E,E-2,4-hexadienal, and E-2-octenal. The composition of the aggregation pheromones of the imagines and the nymphs is different, which partially leads to a separation of adults and nymphs in their hiding places (Siljander et al. 2007, 2008).

The alarm pheromones are a composition of volatile and unpleasant-smelling substances that are released by the nymphs from three dorsal abdominal glands and by the adults from the ventral metathoracic scent glands. The main components are *trans*-oct-2-en-1-al, *trans*-hex-2-en-1-al, butane-2-one, acetaldehyde, and two unknown substances. The composition of the alarm pheromone in nymphs and imagines is different (Levinson and Bar Ilan 1971; Levinson et al. 1974a, b).

***Cimex lectularius*: Development**

The females lay 1–5 eggs per day and in the course of their life about 200 (up to a maximum of 500) eggs, which are fixed on the surface at the hiding places in cracks and crevices. The approximately 1.3 mm long, pale yellow to light brown larvae hatch after 4–21 days. Under favorable

conditions nymphs develop within 1.5–2 months to adults. The development cycle is delayed to 4–7 months at low temperatures and other adverse conditions. Below 13–15 °C no further development occurs, and below 7 °C nymphs and adults stop feeding. The nymphs need a blood meal before molting to the next stage. However, older instars and adults can stay in cold periods for a longer period and starve up to 1 year (Boase 2007; Goddard and DeShazo 2009).

The males do not use the genital tract for insemination but perform the copula by “traumatic insemination.” The male pierces the females abdominal sternite and injects its sperm with the help of a hook-shaped paramere into the spermatheca of the female’s paragenital system through which the sperm migrate to the eggs (Reinhardt and Siva-Jothy 2007; Stutt and Siva-Jothy 2001; Wachmann et al. 2006).

The bed bugs receive vitamins of the D group, which are not present in the blood, from symbiotic microorganisms, which are kept in the mycetomes. These endosymbionts are passed in the ovary to the egg and thus to the next generation (Hypsa and Aksoy 1997; Sakamoto and Rasgon 2006).

***Cimex lectularius*: History and Resurgence**

It is believed that *Cimex lectularius* originally lived in caves and was associated to bats. The species adapted to man, as he began to colonize caves 10,000–20,000 years ago.

Bed bugs were widespread in the industrial nations until the fourth decade of the twentieth century. Due to the widespread use of DDT, improved hygiene, and an increased awareness in the population, the species nearly disappeared in industrialized countries from the human environment and did hardly play a role in the following decades. Since ~1995, a sharp increase in bed bug populations was recorded in Europe, the USA, and Australia. Authors in the UK and the USA described an increase in bed bug problems on the tenfold and more since 1999. Similar observations were published in Australia.

However, bed bugs remained in the nonindustrialized countries at a high level (Newberry and Jansen 1986).

Possible reasons for the resurgence of bed bugs are discussed in the literature (Boase 2007; Doggett et al. 2004; Hwang et al. 2005; Pospischil 2010; Potter 2006; Romero et al. 2007). The increased presence of bed bugs in hotels near an airport indicates that increased travel activity is one important reason for spreading of this species. The detection of bugs in the luggage of travelers and in airplanes is a further indication of the national and international travel as a possible cause. Apartments or units that are subject to a high turnover of residents, including emergency shelters, asylum accommodations, and student hostels, were also recognized as a reason for the fast spreading of bed bugs (Boase 2007).

***Cimex columbarius*: Pigeon Bug**

Cimex columbarius is widely distributed in Europe and associated to pigeons. But other bird species and humans may be also accepted as hosts at least for a short term. The species was formerly common in lofts but more recently it has become rare. Open nests at the walls of buildings are seldom colonized by pigeon bugs. The nocturnal, temporarily ectoparasitic life corresponds to that of *Cimex lectularius* (Wachmann et al. 2006).

***Oeciacus hirundinis*: Swallow Bug**

The swallow bug *Oeciacus hirundinis* is the smallest species of the Cimicidae in Europe.

Its distribution extends over Europe and the Mediterranean region and the west of North Africa to Siberia and Central Asia. The swallow bug is a temporary ectoparasite on swallows and swifts and lives in their nests, where it sucks blood on the young birds. Other bird species are seldom parasitized by *O. hirundinis*. Sometimes bugs invade into buildings after the birds have left the nest in late summer and infest people. Both adults and nymphs hibernate in the swallow nests (Wachmann et al. 2006).

Cinchona

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The bark of the trees of this species were formerly used to extract Quinine as remedy against malarial

fever. See ► [Malaria](#): History of combating the disease.

Cinderella Syndrome

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Red blood cells infected by schizonts of different *Plasmodium* species burst synchronously as soon as the merozoites inside are fully developed. This effect occurs at species specific intervals (Table 1) ranging from 18–72 h. *Plasmodium chabaudi* of rodents initiates bursting of its host cell daily at midnight. Referring to the fairy tale of the girl “Cinderella,” who had been warned not to stay longer than midnight at a ball event since afterwards her coach would become by explosion a

Cinderella Syndrome, Table 1 Timing of the cell cycle of different *Plasmodium* species leading to disruption of the red blood cells and thus setting free synchronously the merozoites

<i>Plasmodium species</i>	Length of cell cycle (h)	Hosts
<i>Pyoelii</i>	18	Rodents
<i>P. berghiei</i>	22	Rodents
<i>P. chabaudi</i>	24	Rodents
<i>P. knowlesi</i>	24	Humans, primates
<i>P. falciparum</i>	48	Humans
<i>P. vivax</i>	48	Humans
<i>P. cynomolgi</i>	48	Primates
<i>P. gonderi</i>	48	Primates
<i>P. pitheci</i>	48	Primates

Cinerin

Chemical Class

Natural products (terpenoid).

Mode of Action

Open state voltage-gated sodium channel blocker.
► [Ectoparasiticides: Blockers/Modulators of Voltage-Gated Sodium Channels](#).

Ciprofloxacin

Antibiotic that is used to treat ► [cyclosporiasis](#) in humans that are intolerant to sulfonamides (500 mg twice daily for 7 days).

Circadian Rhythms

Parasites act or are present at special habitats during fixed hours of the day; e.g., Enterobius females migrate nocturnally from the rectum to the perianal region to lay their eggs; larvae of ► [Loa loa](#) are found in the peripheral blood between 1 pm and 3 pm, while the microfilariae of ► [Wuchereria bancrofti](#) are seen there between 9 pm and 11 pm in the evening. Some mosquito species feed at night, others exclusively during daytime.

Circulating Antigen

ELISA – tests have been developed to detect circulating anodic antigen (CAA) and circulating cathodic antigen (CCA) in serum and urine of patients with schistosomiasis. Both antigens are found in more than 90 % of the infected people and even diagnosed in people, where stool controls remained negative.

Circumsporozoite Protein

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Surface coat of ► *Plasmodium* sporozoites, which consists of an immune-dominant 40–60 kDa protein being characterized by four amino acids repeated 37 times and three or four copies of a smaller repeat dispersed throughout the molecule.

Circumsporozoite-Like Antigen

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes a 1,300 kDa glycoprotein that is found in the micronemes and on the surface of merozoites and sporozoites of ► *Cryptosporidium* species.

Cirripedia

Group of lower ► *Crustacea* (= Entomostraca). The larvae are free-living and swim by cilia. Some attach to rocks, ships etc., produce calcareous shells (e.g., genus *Balanus*) and live as filter

Cirripedia, Fig. 1 *Sacculina carcini* below the “tail” of a brachyceran crustacean (= crab)

organisms. Some (e.g., *Sacculina carcini*) become parasites by entering the body cavity of crabs (Fig. 1). Only an amorphous mass (= which contains and excretes the larvae) is seen outside of a parasitized host, which at its inner side is completely filled by tumor – like growing strands of undifferentiated cells. Thus this group with about 230 marine species is called Rhizocephala (from Greek: *rhiza* = root, *kephale* = head), Fig. 1.

Cirrus

Penis-like structure of Platyhelminthes (► *Platyhelminthes/Reproductive Organs*).

Cittotaenia Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Two species of this genus (syn. *Mosgovoyia*) of anoplocephalid tapeworms parasitize in the intestine of rabbits and hares:

- *C. ctenoides*: strobila 30–80 cm in length, up to 1 cm in width.
- *C. pectinata*: strobila 5–18 cm in length, up to 1.5 cm in width.

Intermediate hosts are oribatid mites. Therapy: Praziquantel; see ► [Cestodocidal drugs](#).

Civil Unrest

Movement of human populations due to different reasons thus spreading agents of diseases, ► [epidemiology](#).

CL

Abbreviation for ► [Cutaneous Leishmaniasis](#).

Clade

A group of organisms that are related by descent from a common ancestor.

Cladogram

A cladistic representation of a phylogeny, whereby only the branching order is displayed (► [Phylogeny](#)).

Clag Genes

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Family of genes being specific for *Plasmodium* species and being involved in cytoadherence processes.

Classification

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

General Information

“Nothing remains as it is.” This sentence is true in particular with respect to the recent situation of taxonomy, which – since its beginnings – has tried to reflect relationships between taxa. The earlier classifications were based on morphological and developmental similarities; and individuals resembling each other were grouped together as a species, similar species as genera, and so on. So much information accumulated that finally two different kingdoms – plants and animals – arose among the eukaryotic organisms, the origin of which, however, remained under constant discussion. Nowadays, the use of molecular biological methods delivers new and deeper insights into the genetic repertoire of organisms and thus other interpretations are called for. When considering the ideas actually discussed (Fig. 1, p. 255), that all recent organisms are a mixture of different hereditary lines, including the genomes of former autotrophic ► [prokaryotes](#), heterotrophic prokaryotes, and heterotrophic eukaryotes, the border between animals and plants becomes obsolete. Thus, the position of the different parasites in this living world has reached the point of new allocation, and discussion is going on about mono- and polyphyletic modes during the evolution of metazoans. When looking at ► [spliced leader](#) RNA, ► [trans-splicing](#), which was originally described as a mechanism of gene expression in parasitic ► [Kinetoplastida](#) and which is now also found in free-living and parasitic helminths, new possibilities (Fig. 2, p. 256) for explaining the radiation of early ► [Metazoa](#) were seen by several authors. Since most of the results obtained are preliminary and, moreover, often contradictory, all recently proposed systematics remain hypothetical and will be changed in

Classification,

Fig. 1 Diagrammatic representation on recent ideas of origin and relationships of living organisms (According to Bardele, Tübingen)

future. The old classifications that are being adapted in most parasitological textbooks are apparently scientifically wrong, but nevertheless useful for categorizing the knowledge. Thus, the only groups that are today fairly stable are the species, the families, and the phyla, although even within them newly discussed strains or systematically unseated groups (such as

► *Pneumocystis* or *Blastocystis* with protozoan and fungal characteristics) are leading to disturbances. In order to provide a survey and the possibility of retrieving facts at a suggested place, both systematic attempts – the new more-correct one and the old better-known one – are presented here one after the other, with special reference to parasitic groups (Fig. 3).

Classification,

Fig. 2 Hypothetical monophyletic evolutionary scheme for the relationship of some early Metazoa and their progeny. This proposal illustrates a potential role for a flagellate ancestor of Metazoa (but not directly the Kinetoplastida) and a proto-flatworm as an ancestor of bilateral Metazoa. Boxed groups represent Metazoa known to have spliced leader ► [trans-splicing](#) (According to Davis)

Clinical and Pathological Signs of Parasitic Infections in Domestic Animals

Arwid Dauschies
 Veterinärmedizinische Fakultät, Institut für
 Parasitologie, Universität Leipzig, Leipzig,
 Germany

General Information

Domestic animals are subject to a wide array of parasite infestations. The course of the infection depends on a variety of factors, such as virulence of the pathogen, infection pressure, environment, susceptibility, and condition of the host. Tissues particularly exposed to parasite invasion are the skin and the mucosal surfaces of the gastrointestinal tract and the respiratory tract, but virtually every tissue and organ may be affected directly or indirectly by parasites. Clinical disease reflects the injury and/or tissue malfunction induced directly by the parasite; however, some parasite species induce systemic disease which is, e.g., associated to toxins, allergy, cardiovascular crisis, or immune complex-related disorders. Parasite

invasion often remains subclinical and thus undiagnosed; however, even such infections affect host condition, and this is of particular relevance for livestock species where loss of productivity due to subclinical disease may be a topic of serious concern. Moreover, subclinical infection with zoonotic parasites both in pet animals (e.g., *Giardia*, *Toxoplasma*, *Toxocara*, *Echinococcus*) or livestock species (e.g., *Trichinella*, larval *Taenia*, *Cryptosporidium*, *Toxoplasma*) is related to increased risk for humans and should thus not be disregarded.

Attack by hematophagous insects such as mosquitoes, tabanids, or biting flies may disturb animals, and in case of serious exposure this will affect the well-being of animals and livestock productivity. Generally hematophagous ectoparasites do not significantly insult their host directly. Arthropod bites mostly induce only small cutaneous lesions that are accompanied by more or less pronounced local inflammatory response and sometimes itching or local hair loss. Secondary infection, necrosis, and ulceration may, however, lead to more pronounced lesions. Saliva of hematophagous arthropods may contain products that are bioactive, toxic, or allergenic, and mass infestation with certain organisms is related to severe disease symptoms (e.g., simuliotoxicosis, tick paralysis). Animals may display dermal pathology that is not directly related to the arthropod attack but secondary due to exaggerated allergic response (e.g., horse summer eczema provoked by *Culicoides*, flea allergy dermatitis). Allergenic compounds produced by ectoparasites play also an important role in the pathology and clinical course of mange resulting from dermal infestation by astigmatic or prostigmatic mites. The clinical picture may differ depending on the features of the parasite and the host species affected. Alopecia, dermal hyperkeratosis, and more or less intensive or local to extensive cutaneous inflammation and itching (which is not typical for canine demodicosis) may be obvious signs of ectoparasite infestation. Itching may lead to excoriation due to intensive scratching or other self-injury.

Moreover, arthropods serve as vectors of disease related to viral, bacterial, or other parasitic

pathogens; however, this aspect is not a topic of this entry.

Helminths and protozoa inhabit more or less specific locations in their host, and some move between tissues during their development, thereby causing lesions at different sites depending on their life cycle. The clinical and pathological consequences of parasite infestation reflect the degree of alteration of the host tissue and the importance its intactness has for preservation of essential functions in the host organism. For instance, adult *Dirofilaria repens* live in the subcutis and do not induce relevant pathology in most cases, whereas *Dirofilaria immitis*, the canine heartworm, may cause severe and even lethal disease. Some endoparasites are of considerable inherent virulence (e.g., *Leishmania infantum*, *Echinococcus* metacestodes), but in most cases clinical disease is visible only under certain conditions such as extreme infection pressure (e.g., chicken coccidiosis), immunodeficiency (e.g., demodicosis), particularly susceptible age-group (e.g., cryptosporidiosis), or other predisposing disease.

In case of parasitism of the gastrointestinal system, diarrhea of variable quality is the most typical symptom of disease. Low-grade infected animals pass feces of normal quality, but the consistency will change to pasty (e.g., piglet isosporosis) or watery (e.g., calf cryptosporidiosis) in situations of clinically relevant exposure. Some parasites induce hemorrhagic diarrhea (e.g., *Eimeria tenella* in chicken, *Ancylostoma caninum* in dogs). Besides blood feces may contain fibrin strands or detached tissue, e.g., in severe cases of bovine coccidiosis. Fever may or may not be present in clinically diseased individuals. Dehydration due to excessive loss of fluid is a major sequel of severe parasitic gastroenteritis possibly culminating in a life-threatening situation. Some parasites, particularly those inhabiting the upper digestive tract such as the stomach (e.g., *Ollulanus tricuspis*) or the esophagus (*Spirocerca lupi*), may induce vomitus in their host. Reduced appetite and altered feed conversion due to gastrointestinal parasitism is associated with poor performance and condition. In severe cases anorexia, lethargy or depression, abdominal pain, edema, exsiccation, and even

death may be observed. The severity of the disease depends on parasite burden, the pathogenicity of the respective species, and the susceptibility of the host (age, condition, immune status).

At postmortem the mucosal surface may appear undisturbed or is more or less distinctly inflamed, swollen, and/or rough. The intensity and type of lesions depend on the intensity of infection, the stage of parasite development, and the features of the parasite. Granulomatous nodules are present during the histotropic phase of nematode development. Adult worms are mostly either attached to the mucosa at the preferred region of the gastrointestinal system or they dwell in the intestinal lumen. They can be easily identified according to their size and typical morphology. However, certain worm species are quite small (e.g., *Echinococcus* spp.), thin (*Strongyloides* spp.), and/or closely attached to the mucosal lining (e.g., *Capillaria* spp.). Therefore, microscopical examination of mucosal scrapings may be required for accurate postmortem diagnosis. The same applies to protozoa in general; however, some *Eimeria* spp. produce typical lesions or parasite foci at their site of multiplication which are suitable for macroscopic diagnosis at postmortem.

Some, even large helminth parasites, such as adult cestodes or ascarids, do not cause relevant mucosal injury in their host although performance may be impaired due to nutrient deprivation. Worms that firmly attach to the mucosa (e.g., hookworms, *Strongylus* spp., *Trichuris* spp.) cause focal destruction of the mucosa at the respective site which may become clinically relevant in case of large worm burden. Intestinal obstruction by high amounts of large worms may induce ileus; however, this is only exceptionally the case. Loss of mucosal surface (brush border, atrophy, or fusion of intestinal villi), inflammatory infiltration, and mucosal edema are typical for many parasitic infections. Destruction of deeper layers of host mucosa, e.g., by certain species of *Eimeria* or bloodsucking nematodes, is related to intestinal bleeding. Petechial or confluent mucosal hemorrhage is seen in such cases, and the intestinal contents will be of dark color. Tissue destruction may develop into mucosal ulcer and

necrosis. Catarrhalis membranes, fibrin coagula, tissue strands, or blood may be visible in the lumen of the affected part of the digestive system. Alteration of gastrointestinal blood flow, e.g., due to occlusion of capillary vessels by migrating worm larvae or fibrin clots (*Strongylus vulgaris*), results in ischemia and infarction leading to tissue necrosis that is lethal if larger areas of the (lower) intestine are affected.

Parasite invasion of the liver by helminths may remain clinically inconspicuous; however, severe disease is sometimes observed. In the latter case, abdominal swelling (sometimes painful), icterus, edema or ascites, and digestive disturbance (intermittent diarrhea, vomiting, etc.) are prominent signs of liver injury. Such animals show general signs of disease including anorexia, lethargy, weight loss, and fever. Anemia and icterus may be further clinical correlates of parasitic liver disease. Disturbed liver function and loss of integrity often participate in the pathogenesis of systemic disease (e.g., immune complex disorders).

At postmortem focal or confluent necrosis is a feature of invasion of liver parenchyma by flagellates particularly in birds (*Histomonas meleagridis*, *Trichomonas gallinae*). The liver is also a preferred site for the development of metacestodes of *Echinococcus*. Many interconnected cysts of variable size with caseous, gelatinous, or fluid contents ("alveolar echinococcosis") or large, fluid-filled cysts ("hydatid echinococcosis") are formed in the liver of the intermediate host. These cestode larval stages reach considerable size, thus displacing liver tissue, and will be easily recognized at necropsy. However, differential diagnosis by microscopical identification of typical structures after necropsy is sometimes necessary. Juvenile cestodes (*Taenia hydatigena*), trematodes (*Fasciola hepatica*), or nematode (e.g., *Ascaris suum*, *Toxocara canis*) larvae cause sometimes extensive parenchymal destruction along their route of migration through the liver. Local bleeding and inflammation are present in the early stage. Lesions are later repaired by connective tissue, and granulomatous fibrous nodules are formed around entrapped larvae (e.g., "milk spots" due to *Ascaris suum*). These reparative procedures are visible by white

foci or strands which disappear after several weeks.

Parasite invasion of the bile ducts is associated with inflammation (cholangitis, cholangiectasia). The wall of the bile ducts is thickened due to excessive proliferation of connective fibrotic tissue, and calcification is obvious at necropsy of cattle chronically infected by *Fasciola hepatica*. Interstitial hepatitis and peribulbar fibrosis are observed in the liver parenchyma which are induced by toxic fluke metabolites. Irritation of bile duct lining by flukes (e.g., *Opisthorchis felineus*) or intracellular parasites (*Eimeria stiedae*) may provoke abnormal proliferation of bile duct mucosa and loss of functionality. The presence of numerous large parasites, inflammation, or extensive proliferation will lead to occlusion of the bile duct lumen.

Parasite infestations of the respiratory system cause moderate or even subclinical respiratory distress in many animal species (e.g., protostrongylids in small ruminants) and are a potential source of discomfort and disturbed performance. Infestation of the nasal cavities by botfly larvae (*Oestrus ovis*) occasionally occurs in sheep. The larvae induce local mechanical irritation of the mucosa and inflammation. Subclinical lungworm infections are quite common in small ruminants, whereas *Dictyocaulus viviparus* is considered to be a highly pathogenic worm in the bronchi of susceptible (young) cattle. Verminous clinical bronchopneumonia is related to general symptoms caused by respiratory disease such as coughing, sneezing, and impeded breathing, often accompanied by fever. Increased nasal discharge may occur, and auscultation will reveal abnormal respiratory sounds. Severely affected animals gasp for breath and breathing frequency is increased. At necropsy mechanical constriction of airways by large nematodes ("lungworms") such as *Dictyocaulus* spp. in ruminants or *Syngamus trachea* in birds, inflammation, and (foamy) bronchial secretion are apparent. Resulting pathological observations of the lung include edema, emphysema, or atelectasis and inflammation. In cattle variable alterations are often located in neighboring lobules giving the lung a mottled appearance, and severely diseased

animals will die without treatment. Secondary infection may aggravate the clinical picture or lead to health impairment even when parasitic invasion by itself is subclinical.

Members of several nematode taxa pass the lung during somatic migration (e.g., ascarids, hookworms, *Strongyloides*). They penetrate from lung capillaries into alveolus which mostly is not accompanied by clinical symptoms. However, in case of high parasite load and in a state of particular sensitivity (young age), the numerous lesions may provoke inflammation and temporary coughing. The lesions may give rise to secondary infection by other pathogens (bacteria, virus) and thus pneumonia.

Protozoan infection of the genital mucosa (bovine tritrichomonosis) induces uterine inflammation, followed by abortion and disturbed fertility. Congenital defects or abortion occurs due to intrauterine transmission of cyst-forming coccidia (*Neospora caninum*, *Toxoplasma gondii*). Abortion results from fetal death or placental necrosis. Genital mucosa is parasitized following sexual transmission of *Trypanosoma equiperdum* which induces inflammation of genital tissue but will subsequently lead to a more severe general disease.

Disorders of the central nervous system (e.g., abnormal locomotion), sometimes lethal, are occasionally associated to parasite infestation. Lesions may be due to destruction caused by migrating nematode larvae (e.g., *Baylisascaris procyonis*) or due to growing metacestodes (*Coenurus cerebralis*, *Echinococcus* cysts). Cysts of *Toxoplasma gondii* and *Neospora caninum* as well as microsporidia such as *Encephalitozoon cuniculi* are neurotropic and have been reported to be related to encephalitis or focal necrosis in the CNS.

Some protozoan species form cysts in muscle fibers which may be large enough to be visible by the naked eye (e.g., *Sarcocystis gigantea*) or are of microscopic size (several species of *Sarcocystis*, *Toxoplasma gondii*). Likewise, *Trichinella spiralis* larvae develop inside myofibers in various animal species, whereas metacestodes of *Taenia* spp. (e.g., *Cysticercus bovis*) are located between muscle fibers. Moreover, migrating

nematode larvae are occasionally found in muscle tissue. Although myositis or myocarditis is sporadically reported, intramuscular parasite stages do not regularly produce clinical symptoms in domestic animals.

Destruction of endothelial host cells by intravascular stages of protozoa (e.g., *Sarcocystis*) opens small lesions that become visible as petechial bleedings. Mechanical irritation of the lining of blood vessels is related to the intravascular phase of somatic migration. The presence of parasites or parasite products in the bloodstream may lead to blood clotting disorders such as disseminated intravascular coagulation (DIC).

Anemia is induced by various parasite species as a result of extensive hematophagous activities, bleeding through lesions, hemostatic crisis, or disturbed hematopoiesis. Intraerythrocytic parasitism (e.g., *Babesia* spp.) eventually leads to destruction of the host cell. Pale mucous membranes and hemoglobinuria are seen in such cases, sometimes accompanied by prehepatic icterus. Destruction of phagocytic cells as seen during leishmaniosis or proliferation of lymphocytes followed by lymphocytolysis that occurs during theileriosis is correlated to severe systemic disease. The participation of various organs and tissues and variability of the clinical picture sometimes observed are related to immune complex disorders in diseases such as babesiosis, leishmaniosis, and heartworm disease.

Conclusions

The clinical and pathological signs of parasitic infection are determined by the pathogenicity of the parasite species involved, the parasite load, the susceptibility and condition of the host, the sensitivity of the invaded tissue/organ to parasitic alteration, and the efficacy of host defense mechanisms. Clinical signs will often not allow correct etiological diagnosis, and serology or molecular methods are necessary in such cases. Pathological alterations are often quite typical. At necropsy, large parasites are easily identified, whereas microscopical examination may be necessary and in fact sufficient in most but not all

cases of invasion by small parasites, such as protozoa.

General Information

It is difficult to give an estimate of the (economic) importance of parasitic diseases at the world level. Firstly, this is because the effect of a particular parasitic disease may vary completely from one region to another. Secondly, our knowledge of some parasitic infections is based primarily on experimental infections, which often differ from natural conditions. Finally, appropriate data are missing for a number of diseases. Some parasites are known to induce severe, sometimes highly fatal clinical syndromes, and have a recognized economic importance. Most of the others only produce subclinical or even asymptomatic infections. However, it has now been established that such subclinical infections cause significant losses due to long-term effects on animal growth and productivity and increased susceptibility to other parasitic or bacterial/viral diseases. Some parasites, even when they are of minor pathological and/or clinical relevance in the animal host, are of considerable zoonotic impact.

Parasitism causes a wide variety of clinical and pathological changes. This is easy to understand as parasites occur in all organs of the host (Fig. 1). However, most signs are nonspecific, and a clinical examination alone is often insufficient to establish an etiological diagnosis. The clinician is therefore dependent on other diagnostic methods such as laboratory examination of feces, blood, and urine.

The pathogenicity of a particular parasite population will depend on the “parasite load” and on the major site of infection. The heavier the infection, the more dramatic is the effect, although there is both a lower and upper threshold. However, in the field many different factors contribute to determine the clinical outcome of a parasitic infection. Age and previous parasite experience increase resistance to infection with most parasites. It is also generally accepted that the plane of nutrition of the animal affects its overall response to the infection, either by affecting the rate of establishment of the parasite or modifying the effects of the infection. Finally, resistance to infection is often reduced by stressful conditions, such as during intercurrent diseases and around parturition (Fig. 2). Caution is needed when applying the results of experimental infections with individual parasites to the field situation in which animals normally acquire several parasite species concurrently. The combined pathophysiological effects of several parasite species may be greater than could be anticipated from the effects of monospecific infections, and secondary infections by other nonparasitic pathogens may also considerably contribute to the course of the disease.

Anorexia

► **Anorexia**, or reduction in voluntary food intake, is a feature of many parasitic infections. The degree of appetite loss can vary considerably. In moderate to heavy infections, food intake can be reduced by 20 % or more. It may be less obvious in lighter infections. The degree of appetite loss has been shown to vary not only with the

Clinical Pathology, Animals, Fig. 1 General outline of host–parasite relationships

Clinical Pathology, Animals, Fig. 2 Relationship between parasite load, immunity, and nonspecific resistance of host and severity of disease

level and duration of parasitism but also with the level of protein nutrition.

The evidence from the literature indicates that the appetite suppression, observed in ruminants parasitized with gastrointestinal nematodes, results from the presence of worms in the lumen or mucosa of the alimentary tract. It seems that nematode-associated pathology/histopathology is not a prerequisite for this response and that the mere presence of parasites is sufficient to provoke a loss in appetite. The putative mechanisms involve parasite excretory/secretory (ES) products that provoke host inflammatory/immune/endocrine responses in a neuroendocrine cascade of events that leads to the release of appetite inhibitors from the hypothalamus.

Production Losses

Parasites can have a range of effects on animal production. A reduction in growth rate and even losses of weight are probably the most widely described effects of parasitism. It has been recorded for infections with ► [protozoa](#), ► [nematodes](#), cestodes, ► [trematodes](#), and arthropods and is best studied in cattle, sheep, and pigs. The effect on body weight is independent of the site of infection, and the heavier the infection the more dramatic the effect. However, there is both a lower and upper threshold in intensity of infection where weight ceases to be affected. In the latter case, this is because of the early death of the animal. In general, at equal parasite exposure or worm burdens young animals or animals on a poor plane of nutrition are more severely affected than those maintained on a better diet, or adults. Parasites may have long-term effects on productivity. For instance, suckling calves or piglets suffering during the first weeks of life from diarrhea due to *Cryptosporidium parvum* or *Isospora suis*, respectively, will in many cases not reach the expected level of productivity thereafter. In addition to changes in body weight, alterations in body composition also occur. These can be of considerable importance when assessing the economic impact of parasitism. Most authors have found that infected animals had a higher percentage of

water and a lower deposition of fat, protein, and skeletal calcium and phosphorus, compared with parasite-free controls. The reasons for impaired growth or loss of weight are complex. They have been studied more particularly in intestinal trichostrongylid infections. Because of the loss of appetite, the enteric losses of proteins, and the increased rates of intestinal metabolism, there is a net movement of amino acid nitrogen from the muscles, and possibly the skin, to the liver and intestines. This decreases the availability of nitrogen for growth, milk, and wool production. The drop in appetite was responsible for nearly 73 % of the difference in live weight gain between calves infected with ► [Ostertagia ostertagi](#) and control animals. More recently, the effect of helminths on carcass weight of beef cattle was studied using liver condemnation data or meat juice ELISAs (*Ostertagia* and *Fasciola*) and found reductions in carcass weights between 0.5 % and 2 %.

There has been a considerable controversy regarding the effect of parasites on milk production. However, in recent years evidence has accumulated that the impact can be substantial. In an extensive review of 87 published clinical trials, it was found that in cattle infected with gastrointestinal nematodes, a positive milk yield response after anthelmintic treatment was observed in 80 % of the trials with a median increase of 0.6 kg milk/cow per day. After taking into account small-study effects and publication bias, a meta-analysis on 75 published trials estimated the milk-production increase after anthelmintic treatment on 0.35 kg/cow per day. In more recent trials ($n = 6$), published after 2000, the average milk yield increase after treatment in pastured dairy herds was around 1 kg/cow per day. This number agrees markedly with the results of studies that investigated the relationships of *O. ostertagi*-specific antibody levels in bulk-tank milk and annual average milk yield, where an increase in the *O. ostertagi*-specific antibody level over the interquartile range was associated with a drop in milk yield of 0.9–1.2 kg per cow per day. Subclinical infections with ► [Fasciola hepatica](#) affect milk yield in cattle by approximately 3 %. In ewes infected with gastrointestinal

nematodes, increases in the whole lactation milk production of 9–40 % were recorded following anthelmintic treatment. It has also been shown that arthropod parasites such as horn flies, stable flies, cattle grubs, and ► [mites](#) can reduce milk production by up to 40–60 %.

Many helminth infections adversely affect the quantity and quality of wool. Wool growth can be reduced by up to 66 % in some parasitic infections. The reduction in growth rate of wool is accompanied by decreases in staple length and fiber diameter. There are indications that these effects occur at levels of infection below the threshold normally considered to affect body weight.

Reproductive Performance

The impact of parasitism on reproductive performance is of major economic importance. Parasites such as ► [Toxoplasma gondii](#) in sheep and goats and ► [Tritrichomonas foetus](#) and ► [Neospora caninum](#) (syn. *Hammondia heydorni*) in cattle often induce ► [abortion](#). Preventive treatment of gastrointestinal trichostrongylosis or fasciolosis in ruminants may result in earlier breeding, higher pregnancy rates, and better birth weights. In contrast, severe general parasitic disease in young animals or parasite-induced inflammation in the reproductive system bears the risk of insufficient reproductive performance afterward.

Clinostomum

Genus of bird, ► [Digenea](#).

Clitellum

Belt-like zone in ► [Annelida](#) (e.g., ► [Hirudo medicinalis](#), ► [leeches](#)) that excretes mucous material, which is used to form the ► [cocoon](#) around eggs.

Cloaca

Common exit of intestine and male reproductive system (e.g., in ► [nematodes](#), Sauropsida), ► [Nematodes/Reproductive Organs](#).

Cloacina

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of *nematodes* (Strongyloidea) infecting kangaroos and wallabies in Australia. About 110 species are known, e.g., *C. atthis*, *C. clymene*.

Clone

Name

Greek: *klon* = *kladon* = offspring.

Population of protozoans that derived from a single cell by asexual reproduction. Thus all cells have an identical genetic appearance.

Clonorchiasis

Synonyms

Opisthorchiasis, Man

Clonorchis sinensis

Zhongdao Wu¹ and Heinz Mehlhorn²

¹Department of Parasitology, Zhongshan School of Medicine, Key Laboratory for Tropical Diseases Control, The Ministry of Education, Sun Yat-sen University Guangzhou, Guangzhou, China

²Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *klon* = branching system; *orchis* = testicle (the genus names describe that the testes are branching). Latin: *sinensis* = from China. English: Chinese liver fluke.

Geographic Distribution/Epidemiology

In East and South Asia, especially in China, Thailand, Korea, and Japan, about 50 millions of humans and some more dogs and cats are infected.

Morphology/Life Cycle

The dorsoventrally flattened adult worms (Figs. 1, 2, and 3) are hermaphrodites, reach a length of 10–20 mm and a width of 3–5 mm, and are able to stretch themselves considerably. These translucent worms live in the bile ducts of humans and fish-eating animals (e.g., also in dogs and cats), and their tegument does not contain hooks or scales (it is smooth). Characteristic for this species are the two testes, which lay in the terminal portion of the body and are branched. The anterior one shows 4 branches, the posterior one 5. Their single excretory ductules (vasa efferentia) unite themselves to form the vas deferens which has its opening (armed by a penis-like cirrus) in a furrow below the ventral sucker. This opening is situated in the close neighborhood to the opening

of the uterus, which releases the fertilized eggs, but also becomes filled with sperms of another worm during copulation or with sperms from its own male system (in the absence of a foreign sexual partner). The life cycle involves two types of intermediate hosts (snails and fresh water fish), where asexual reproduction occurs and the fish eating-final host (Fig. 1). First intermediate hosts are water snails of the genera *Semisulcospira*, *Bulinus*, *Parafossarulus*, etc., while freshwater fish serve as second intermediate host. The meat of the latter contains the infectious, tail-less spherical metacercariae, which have been developed from motile cercariae after their penetration into the fish (Fig. 1). These metacercaria grow up in humans (the final hosts), where they are located inside the gall bladder system. In case dogs, cats, or even pigs ingest infected remnants of raw fish, they may become final hosts, too.

Symptoms of Disease (Clonorchiasis)

The symptoms and their severity depend on the number of ingested worm larvae. Infections with 20–200 adult worms are common in humans living in endemic regions and lead to abdominal pain, liver swelling, slight icterus, and problems in digestion. However, infections with 1,000 or more worms lead to massive, i.e., bloody diarrheas, ascites, anemia, formation of edemas, and also liver cirrhosis. All these symptoms may result in the death of the patients, which may also develop liver abscesses or collagenous carcinomas before.

Diagnosis

Microscopical determination of the tiny, operculated, brownish eggs, which reach a length of about 35 µm (Fig. 4). These eggs can be obtained from the fluid of the bile ducts or when using concentration methods (i.e., S.A.F.C.) from feces. Serodiagnosis is not species specific, while PCR shows good results as well as sonography of liver and bile ducts.

C

Clonorchis sinensis, Fig. 1 (continued)

Clonorchis sinensis, Fig. 2 Light micrograph of an adult worm of *C. sinensis* being laterally stretched

Infection

Orally ingestion of infectious metacercariae in raw or undercooked fish. Due to lacking immunity, the amount of adult worms may become constantly increased.

Prophylaxis

Avoidance of eating raw or undercooked freshwater fish in endemic regions.

Clonorchis sinensis, Fig. 3 Scanning electron micrograph of the ventral side of an adult worm of *C. sinensis*. Note the oral and ventral suckers and the two openings which are situated in a small furrow below the ventral sucker

Incubation Period

In cases of severe infections: ~2 weeks; in cases with only a few worms, no symptoms may occur.

Clonorchis sinensis, Fig. 1 Diagrammatic representation of the life cycles of *Clonorchis sinensis* (Loos 1907) and *Opisthorchis felineus*. ^aThis species is probably synonymous to *Hammondia heydorni* representing a pathogenic strain that introduces under special conditions the described abortions in cattle and dogs

^bResults according to Peteshev (personal communication); these findings, however, were not confirmed for the Berlin strain of Prof. Heydorn

^cThe species of this genus have two types of final hosts

Coccidia, Table 6 Some common species of the Adeleidea

Species	Host	Hosts/habitat	Vector/habitat	Mode of infection/transmission
Significant Adeleidea				
<i>Adelina deronis</i>	1	Oligochaetae (<i>Derolimosia</i>)/body cavity	—	Oral uptake of oocysts/sporocysts
<i>A. cryptocerci</i>	1	Roaches (<i>Cryptocercus</i>)/fat body	—	Oral uptake of oocysts/sporocysts
<i>A. tribolii</i>	1	Red flour beetles (<i>Tribolium</i>)/hemocoel	—	Oral uptake of oocysts via cannibalism
<i>Klossia helicina</i>	1	Snails (<i>Helix</i> , <i>Cepaea</i> , <i>Succinea</i>)/kidney epithelium	—	Oral uptake of oocysts/sporocysts
Adeleidea of doubtful systematic position				
<i>Haemogregarina stepanowi</i>	2	Water tortoises (<i>Emys orbicularis</i>)/erythrocytes, bone marrow	Leeches (<i>Placobdella</i> sp.)/intestine	Blood meal of vector
<i>Hepatozoon muris</i> (syn. <i>Perniciosum</i>)	2	Rats, mice/liver cells, leukocytes	Rat mites (<i>Echinolaelaps</i> sp.)/hemocoel	Blood meal of vector
<i>H. erhardovae</i>	2	Bank voles (<i>Clethrionomys</i> sp.)/lung, leukocytes	Rat fleas/hemocoel	Blood meal of vector
<i>H. aegypti</i>	2	Snakes (<i>Spalerosophis diadema</i>)/Lung, erythrocytes	Mosquitoes (<i>Culex pipiens</i>)/body cavity	Blood meal of vector
<i>Karyolysus lacertae</i>	2	Lizard (<i>Lacerta</i> sp.)/endothelial cell of blood vessels, erythrocytes	Mites (<i>Liponyssus saurorum</i>)/gut epithelium, hemocoel, yolk	Feeding with shed oocysts or infected whole mites, which were infected during blood meal

Coccidia, Table 7 Some blood parasitizing genera of doubtful systematic position

Species	Host	Tissue	Vector	Mode of infection
<i>Lankesterella minima</i>	Frog (<i>Rana esculenta</i>)	Sporozoites: red blood cells	Leech (<i>Placobdella marginata</i>)	Mechanically during blood sucking, by eating the leech
<i>Atoxoplasma</i> spp.	Birds	Merozoites: RES Leukocytes	Mites, mosquitoes	Bite, by eating the vector
<i>Schellackia bolivari</i> (syn. <i>Lainsonia</i> , <i>Gordonella</i>)	Lizards	Merozoites: midgut Sporozoites: red blood cells	Mites	By eating the vector

- **Monoxenous development:** The whole development is restricted to the tissues of a host individual. The species may be strictly host-specific (using only a single host species, e.g., ► *Isospora* spp., ► *Eimeria* spp.) or not (e.g., ► *Cryptosporidium* spp.) and are found in several host types.
- **Di- or heteroxenous development:** Parasites belonging to this group have at least two different hosts during their life cycle: a final host (where the sexual phase proceeds), and an intermediate host (with continuing asexual reproduction) or a ► **paratenic host**, inside which no development occurs but

Coccidia,

Fig. 1 Diagrammatic representation of numbers and relationships between oocysts, sporocysts, and sporozoites in different genera of Eimeriidae. In the genera without sporocysts the numbers of sporozoites per ► **oocyst** are given. In the case of *Cryptosporidium* the smooth oocyst wall disappears and is transformed into the ► **sporocyst** wall. Thus, this genus might also be placed in the second row, but it is probably more related to ► **gregarines**

NUMBER OF SPOROZOITES PER OOCYST	NUMBER OF SPOROZOITES PER SPOROZYST

only an accumulation of infectious stages (► *Cystoisospora* spp.). This alternation of hosts may be: facultative, e.g., ► *Cystoisospora* spp., *Toxoplasma gondii*, ► *Neospora caninum*, or obligatory, e.g., ► *Aggregata eberthi*, *Hammondia* spp., ► *Sarcocystis* spp., ► *Frenkelia* spp., the ► *Haemosporidia*, ► *Piroplasms*, and some species of the ► *Adeleidea*. In some genera (► *Besnoitia*; ► *Globidium*), the life cycles of the species are poorly understood,

so their final classification remains doubtful (Fig. 2).

Important Species

Tables 1, 2, 3, 4, 5, 6, and 7.

Life Cycle

See Figs. 1 and 2.

Coccidia, Fig. 2 Life cycles of different coccidian tissue-cyst-forming genera, the gamogony (GA) of which always occurs in the intestinal epithelial cells of final hosts (FH). (a) ► **Isospora** (e.g., *I. serini* of canaries, *I. lacazei* of sparrows): homoxenous (i.e., one-host-type) cycle. Oocysts are excreted unsporulated (B1); after ► **sporulation** (compare C1) they become infectious to other hosts of the same species. Schizogony (SC) is not restricted to epithelial intestinal cells, but also occurs in the gut wall and extraintestinally. (b) ► **Cystoisospora** (e.g., *C. felis* and *C. rivolta* of cats, *C. ohioensis* of dogs): heteroxenous cycle. Oocysts are excreted unsporulated (B1). An intermediate host (B2) may facultatively be involved in addition to the typical development (SC, GA, SP) inside the intestine of the final host. Rodents and/or cattle are infected by oral ingestion of sporulated oocysts. The sporozoites (SP) enter numerous types of host cells, but remain there unchanged in a ► **parasitophorous vacuole** (PV) until this cell is eaten by the final host. Since there is no parasitic development inside the intermediate host, it must be considered as a transport or ► **paratenic host**. (c) ► **Frenkelia** (e.g., *F. clethrionomyobuteonis*): heteroxenous cycle with an obligate alternation of final (hawk) and intermediate (bank vole) hosts (like ► **Sarcocystis**). The oocysts are excreted fully sporulated (C1) and must be ingested by the intermediate host. Inside the liver cells (C2), typical schizonts (S) produce merozoites, which lead to formation of septated tissue cysts (TC) in brain and cord (C3). The cysts contain dividing merocytes and finally motile cyst merozoites (► **Bradyzoites**). The latter are infectious to the final hosts,

where they (when oral ingestion occurs) initiate gamogony inside the gut cells. (d) ► **Besnoitia** (e.g., *B. wallacei*): obligatory two-host cycle. Oocysts are excreted unsporulated by the final host cat (D1); after sporulation they must be ingested by intermediate hosts (rats, mice), where reproduction initially occurs by ► **endodyogeny** in many cells (appearing as ► **pseudocysts**; D2). Later, tissue-cysts (D3) are formed inside fibroblasts, leading to cysts that are often macroscopically visible. The latter exclusively contain cyst merozoites (never ► **merocytes**), which are infectious to final hosts when ingested. After experimental transmission, cyst merozoites of several ► **Besnoitia** species repeat the developmental steps D2 and D3 in other intermediate hosts. (e) **Hammondia** (e.g., *E. hammondi*): obligatory alternation of two hosts. Oocysts are excreted unsporulated (E1) by the final host cat; after sporulation they must be ingested by intermediate hosts (mice, rodents), where rapid asexual reproduction occurs in lymphoid cells (E2); this is followed by formation of tissue-cysts (TC) in striated muscles (E3). The cyst merozoites are finally infectious to final hosts (FH), where they initiate schizogony in epithelial cells (SC). This species is discussed as strain of ► **T. gondii**. Infection of final hosts (FH) by their own excreted oocysts is only possible in the genera ► **Isospora** and ► **Cystoisospora**. FH final host, GA gamogony, IH intermediate host, N nucleus, NH nucleus of the host cell, PS pseudocyst, PV parasitophorous vacuole, S ► **schizont**, SC schizogony, SP sporogony, SZ ► **sporozoite**, TC ► **tissue cyst** (for more details see Tables 2 and 5 of ► **Coccidia**)

Coccidia of Swine: *Eimeria* Species, *Cystoisospora* (syn. *Isospora*) *suis*

Anja Joachim¹ and Lukas Schwarz²
¹Department of Pathobiology, Institute of Parasitology, University of Veterinary Medicine Vienna, Vienna, Austria
²Department for Farm Animals and Veterinary Public Health, University Clinic for Swine, University of Veterinary Medicine Vienna, Vienna, Austria

General Information

In swine, coccidia (order Eimeriida, family Eimeriidae) of the genera *Eimeria* and *Cystoisospora* (syn. *Isospora*) parasitize the intestinal tissue. While the taxonomy of the genus *Eimeria* is unequivocal, debates are being raised over the naming of the genus *Isospora*, and it was recently suggested to name all species that occur in mammals as *Cystoisospora* (Barta et al. 2005). Consequently, both names are found in literature as synonyms.

Currently eight species of *Eimeria* and one of *Cystoisospora* are described in swine (Table 1) which are all highly host specific and distributed worldwide in both farmed pigs and wild boar. The prevalences depend on the age group and the management conditions for the examined animals.

Infection takes place by ingestion of fully sporulated and infectious oocysts from the environment. Sporozoites are released from the oocysts and invade the epithelial cells of the small intestines, less commonly those of the colon. While porcine *Eimeria* produce several (usually two) generations of meronts, *C. suis* develops into meronts of different types which do not develop consecutively. After this asexual development, merozoites differentiate into gamonts and complete their life cycle by fusion of micro- and macrogamonts and subsequent formation of an oocyst wall. Unsporulated oocysts are excreted with the feces and sporulate in the environment. Once fully developed into infectious sporulated oocysts, the parasites remain viable for months under optimal conditions (high humidity and moderate temperature) and provide a continuous source of infection for susceptible individuals.

In comparison to *Eimeria*, *C. suis* has a considerably faster development. From the time of infection to the completion of sporulation, it takes less than 1 week (including a sporulation period of 1 day under ideal conditions such as those found in warm and humid farrowing pens),

Coccidia of Swine: *Eimeria* Species, *Cystoisospora* (syn. *Isospora*) *suis*, Table 1 Characteristics of eimeriid coccidia (*Eimeria*, *E.*; *Cystisopora*, *C.*) infecting swine (Modified after Dauschies 2006)

Species	Mean oocyst size [µm]	Oocyst morphology	Sporulation time [days]	Prepatent period [days]
<i>E. deblickei</i>	18.8 × 14.3	Smooth, colorless to light brown	5–7	7
<i>E. suis</i>	18.2 × 14.0	Smooth, colorless	5–6	10
<i>E. scabra</i>	31.2 × 11.8	Rough, brown; micropyle	8–9	8–10
<i>E. perminuta</i>	13.3 × 11.7	Rough, yellow	10–12	
<i>E. spinosa</i>	20.6 × 16.2	Rough, brownish with spikes	9–10	8–9
<i>E. polita</i>	25.9 × 18.1	Slightly rough, light brown	5–8	8–9
<i>E. porci</i>	32.2 × 15.7	Smooth, colorless to light brownish; micropyle	6–8	7
<i>E. neodeblickei</i>	21.2 × 15.8	Smooth, colorless	13	10
<i>C. suis</i>	20.6 × 18.1	Smooth, colorless, thin wall	1–2	4–7

Coccidia of Swine:
***Eimeria* Species,**
***Cystoisospora* (syn.**
***Isospora*) *suis*,**

Fig. 1 High-density excretion of *Eimeria* oocysts can occur in individual animals and is accompanied with diarrhea in such cases (flotation sample from a gilt with recurrent diarrhea, 10× magnification)

while *Eimeria* species require at least 5 days for sporulation and have a minimum prepatent period of 5–7 days, depending on the species. *Eimeria* oocysts are excreted for about 1 week on average, while for *C. suis*, the patent period can vary from 1 day to more than 1 week. Frequently, oocysts of *C. suis* are excreted in several peaks, each phase lasting 2–3 days, so that after a prepatent period of 5 days, excretion starts and wanes again with a break of 2–3 days and a second shedding phase around 12–13 days after infection. This biphasic excretion pattern supports the hypothesis that extraintestinal development takes place in *C. suis* and restarts another excretion phase upon the parasites' return into the gut (which is not described in *Eimeria* species); however, definitive proof for this phenomenon is still lacking.

Clinical Relevance

Epidemiological studies have shown that *Eimeria* species can occur in all age groups (piglets, growers, and adult pigs) but are usually found in higher numbers in sows. The prevalence and intensity seem to be related to the gestation cycle of the sows (Joachim and Dauschies 2000). *E. deblickei*, *E. scabra*, *E. polita*, and *E. spinosa* are considered to be more pathogenic than the

other species. Under poor hygienic conditions (poor cleaning, wet bedding), the infection pressure can reach a stage where infections, especially of younger animals in combination with stress, e.g., weaning, can lead to clinical eimeriosis with loose feces/diarrhea and shedding of oocysts in high numbers (Fig. 1), but usually clinical signs are absent in infected animals. By contrast, *C. suis* is almost exclusively found in suckling piglets. Due to a prominent age resistance, the ability of the parasite to multiply and cause disease quickly decreases as the host matures, and in animals older than 3 weeks of age, patent infections and clinical disease are rare (Worliczek and Joachim 2011). Cystoisosporosis is one of the most important causes of neonatal diarrhea in intensive pig production worldwide. After an incubation time of 4–6 days, piglets show pasty to watery, nonhemorrhagic, yellowish diarrhea (Fig. 2). They continue to suckle, but heavily affected piglets become desiccated, and the loss of resorptive intestinal surface (a consequence of the sloughing of the infected epithelium) leads to a reduction in growth and even weight loss – the most important clinical consequence of piglet cystoisosporosis. Affected litters vary greatly in weight by the end of the suckling period, and the number of runts in a litter is increased. The annual financial loss due to porcine cystoisosporosis was calculated to be

up to € 100 per sow (Kreiner et al. 2011). Although morbidity is high in affected litters, mortality due to *C. suis* infections is usually low unless it interferes with the intestinal microbiota; simultaneous infections with *C. suis* and the bacterial pathogen *Clostridium perfringens* (Type A) lead to necrotic enteritis with lethal outcome (Mengel et al. 2012).

Currently it is unclear why *C. suis* infections are largely restricted to neonates. The immature immune system of newborn piglets which is unable to mount an adequate response against primary infections may contribute to the high susceptibility of neonates to infection – the

intestinal compartments of the immune system do not contain substantial amounts of immune cells in the first 3 weeks of life (for review, see Worliczek and Joachim 2011). As with other neonatal infections, maternal factors appear to play a role in immunity, although colostral antibodies of naturally infected sows do not confer protection against experimental infections in their offspring (Schwarz et al. 2013).

Diagnosis

Detection of coccidia is routinely carried out using fecal flotation techniques. Due to the short patency and the high fat content of suckling piglets' feces, detection of *C. suis* is sometimes difficult. Autofluorescence detection microscopy increases the sensitivity of *C. suis* oocyst detection (Dauguschies et al. 2001) (Fig. 3). Differentiation between species is accomplished morphologically as sporulated oocysts are easily distinguished and can be carried out in a semiautomated manner using computer software (Plitt et al. 1999).

After sporulation, *Eimeria* oocysts contain four sporocysts with two sporozoites each; *Cystoisospora* oocysts contain two sporocysts with four sporozoites each (Fig. 4). Sporocyst residual bodies are present in all porcine coccidia, but in contrast to *Eimeria*, *C. suis* oocysts do not contain Stieda bodies or pole bodies.

Coccidia of Swine: *Eimeria* Species, *Cystoisospora* (syn. *Isospora*) *suis*, Fig. 2 *Cystoisospora suis* infection in neonatal piglets is frequently accompanied by yellow, semi-liquid to liquid diarrhea at the age of around 10 days

(c) *Cystoisospora suis* (sporulated) in phase contrast microscopy, 40× magnification

Prevention and Treatment

As with all coccidia, removal of oocysts from the environment reduces infection pressure; however, in closed pig-rearing systems, total elimination is difficult to achieve. All-in-all-out systems with cleaning and disinfection using chemicals that are efficacious against coccidia can help to reduce the infection pressure (Dauguschies et al. 2013). Several chemotherapeutics have been evaluated against swine coccidia. Sulfonamides can be used parenterally, but repeated application is necessary to achieve clinical and parasitological effects (Joachim and Mundt 2011). Currently the drug of choice for routine metaphylaxis of piglet cystoisosporosis on farms where the disease has been diagnosed is toltrazuril which is applied in a single dose during the prepatent period (i.e., before the onset of oocyst excretion) and can effectively prevent both oocyst excretion and diarrhea (Joachim und Mundt 2011).

Therapy

Treatment see ► [Coccidiocidal Drugs](#).

Coccidiocidal Drugs

Economic Importance

Most of the anticoccidials used for the control of ► [coccidia](#) proper in livestock and poultry are approved by government agencies for the prevention of coccidiosis in chickens (Table 1, p. 270). Despite the use of anticoccidials in continuous medication programs, global losses chiefly due to subclinical coccidiosis in broiler poultry is estimated at up to US\$750 million. The enormous expansion of broiler production over the last 16 years (e.g., in USA: 1991/2006 = 6.1/8.9 billion birds = plus 45.9 %) has been reflected in the world market for anticoccidial drugs. In 1991 the total turnover per year was about US\$450 million. This figure includes in-feed anticoccidials (~80 % ionophores) at about US\$370 million, in-water anticoccidials at US\$30–40 million, and biologicals at US\$25–30 million; the broiler market with about 80 % of the total has been large enough to stimulate major screening and development programs in the American and European pharmaceutical industries. However, the rapid emergence of drug resistance can result in a short market life for some drugs (less than 6 months for buquinolate). However, high cost of obtaining government clearance, and the delays involved, have all discouraged pharmaceutical companies. Discovering, characterizing, developing, and registering a new drug may take 8–10 years. The risk of drug resistance may also jeopardize any hope of benefit from the high capital expenditure on registering a new anticoccidial. Several pharmaceutical companies have consequently taken a new approach and abandoned anticoccidial-screening programs although the use of novel high-throughput screening methods would permit large numbers of compounds to be investigated within short periods of time. In future the most promising alternative to

Coccidiasis, Man

Infectious diseases of the human small intestine caused by various ► [coccidians](#) (► [Isosporosis, Man](#), ► [Cyclosporiasis](#), ► [Cryptosporidiosis, Man](#), ► [Sarcosporidiosis, Man](#)).

Main Clinical Symptoms

► [Diarrhoea](#), ► [vomiting](#), loss of weight.

Incubation Period

2–13 days.

Prepatent Period

7–9 days.

Patent Period

Two weeks until 1–2 months (in case of ► [AIDS](#) patients).

Diagnosis

Microscopical determination of oocysts in fecal samples.

Prophylaxis

Avoid contact with human feces.

Coccidiocidal Drugs, Table 1 Anticoccidial drugs used in the poultry industry

Chemical group nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*Brand names (manufacturer, companies, distributors), WT, other information	Comments on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
Sulfonamides (introduced around 1940) (approx. 120–250);	*Brand names (manufacturer, companies, distributors), WT, other information (*Various brand names and suppliers) Limitations: do not use for <i>prevention</i> of coccidiosis recommended dose levels may vary and depend on drug and dose form (in feed or in water)	Opened up the field for practical use; sulfonamides (<i>sulfas</i>) have a broad spectrum of activity against <i>Eimeria</i> spp. of the anterior and lower part of the intestine but only a moderate effect on <i>E. tenella</i> (residing in ceca) of chickens; in cattle, swine, and rabbits prophylactic feeding of <i>sulfaguanidine</i>, <i>sulfaguanoxaline</i> and others (not approved indication) may prevent clinical signs and reduce oocyst production thereby allowing development of protective immunity; drug resistance had limited their use as prophylactics in the past; sodium salts of sulfas are usually water soluble and render them useful for <i>curative treatment</i> of coccidiosis in ruminants, swine, (game) birds, and dogs (withdrawal time may exceed 14 days in food-producing animals); sulfas are active against first- and second-generation schizonts and probably against sexual stages; their action seems to be coccidiocidal at higher doses and coccidiostatic at lower doses; higher doses used in therapy often cause toxicity (hemorrhagic syndrome, kidney damage, growth depression); sulfas interfere with cofactor synthesis, i.e., block dihydropterotate synthetase and hence synthesis of tetrahydrofolate (cofactor is required for cellular methylation reactions) in the early phases of folate synthesis; their action can be nullified by excess p-aminobenzoic acid (PABA); long-acting sulfas (e.g., sulfadoxine, sulfadimethoxine) combined with <i>diaminopyrimidines</i> (e.g., pyrimethamine; other related compounds are ormetoprim, diaveridine, pyrimethamine, and trimethoprim) are highly active antimalarials, anticoccidials, and antibacterials; these combinations may be useful for treating various types of protozoan infections such as toxoplasmosis, sarcocystosis, and neosporosis, various bacterial infections, and human malaria; diaminopyrimidines are dihydrofolate reductase/thymidylate synthase = DHFR/TS inhibitors showing synergistic effects with sulfas due to effects at different sites in the folate biosynthesis; limitations: sulfas, and combinations of sulfas with DHFR/TS inhibitors are not approved for <i>prevention</i> of coccidiosis in poultry or other animals under European Commission Guidelines (additives in feeding stuffs), and feed regulations of Food and Drug Administration (FDA) in the USA and elsewhere, except <i>ormetoprim</i> combined with <i>sulfadimethoxine</i>, the only DHFR/TS-sulfa combination presently available in the USA as an aid for the prevention of coccidiosis in poultry

<i>Sulfaguanoxaline</i>		
<i>Sulfamerazine</i> , and others		

Diaminopyrimidines Sulfadimethoxine/ormetoprim *1 (113.5/68.1 chickens: broilers, replacements, Chukar partridges) (56.75/34.05 turkeys: not laying eggs for human consumption) (454/272.4 for 7 days ducks excluding layers) *2 (113.5/68/22.7 chicken broilers)	1*Rofermaid 40 (feed as a sole ration) 2*Rofermaid Plus Roxarsone (Alpharma, USA), Type A medicated Articles (feed as a sole source of organic arsenic) WT: chickens, turkeys, ducks: 5 days; Chukar partridges: not released into wild before 18 weeks and can only be used up to 8 weeks of age	1*approved indications: <i>chickens</i> (broilers, replacements) as an aid in prevention of coccidiosis caused by all <i>Eimeria</i> spp. namely, <i>E. tenella</i>, <i>E. necatrix</i>, <i>E. acervulina</i>, <i>E. brunetti</i>, <i>E. mivati</i>, and <i>E. maxima</i> and bacterial infections due to <i>Haemophilus gallinarum</i> (infectious coryza), <i>Escherichia coli</i> (colibacillosis), and <i>Pasteurella multocida</i> (fowl cholera); <i>turkeys</i>: as an aid in prevention of coccidiosis caused by all <i>Eimeria</i> spp. namely, <i>E. adenoeides</i>, <i>E. gallopavonis</i>, and <i>E. meleagris</i> and bacterial infection due to <i>P. multocida</i> (fowl cholera); Chukar partridges: for prevention of coccidiosis caused by <i>E. kofoidi</i> and <i>E. legionensis</i>, <i>limitations:</i> feed continuously to young birds up to 8 weeks of age as sole ration; ducks: as an aid in control of bacterial infections due to <i>E. coli</i>, <i>Riemerella anatipestifer</i>, and severe challenge of <i>P. multocida</i> (fowl cholera), limitations: feed as a sole ration for 7 days, withdraw 5 days before slaughter; medication should be started at the first signs of infection; not for breeding ducks, do not feed to ducks producing eggs for food; 2* approved indications: <i>chickens</i> (broilers) as an aid in prevention of coccidiosis caused by all <i>Eimeria</i> spp. namely <i>E. tenella</i>, <i>E. necatrix</i>, <i>E. acervulina</i>, <i>E. brunetti</i>, <i>E. mivati</i>, and <i>E. maxima</i>, and bacterial infections due to <i>H. gallinarum</i> (infectious coryza), <i>E. coli</i> (colibacillosis), and <i>P. multocida</i> (fowl cholera), growth promotion and feed efficiency, improving pigmentation, WT: 5 days
2,4-Substituted aminobenzoic methyl ester Ethopabate (cf. combination with amprolium ↓)	It has a good innate activity against <i>E. acervulina</i> but not so against <i>E. tenella</i> (it has no activity against <i>E. tenella</i>); drug is usually used only in combination with other anticoccidials (cf. amprolium); ethopabate (an aryl-amide containing one phenyl ring belonging to monocyclic aromatics) is a safe drug in mammals and birds; it is an analogue and thus competitor of PABA (p-aminobenzoic acid), which is required for the synthesis of folic acid by the parasite; ethopabate interferes (like sulfonamides) with the dihydropteroate synthetase reaction (conjugation of a pteridine moiety and PABA); however, PABA excess can nullify action of ethopabate	First commercial use of drug products 1968; it arrests sporozoite and trophozoite development (= coccidiostatic effect: withdrawal of drug leads to relapse of infection); it is active against all <i>Eimeria</i> spp. in chickens but considerable problems have been reported with <i>E. acervulina</i>; drug resistance problems limit its use to shuttle programs (e.g., last 1–3 weeks of broiler grow-out); it is synergistic when combined with chemically related 4-hydroxy-quinolines; it is very safe for chickens and safe in mammals; approved indications: as an aid in prevention of coccidiosis caused by <i>E. tenella</i>, <i>E. necatrix</i>, <i>E. acervulina</i>, <i>E. maxima</i>, <i>E. brunetti</i>, and <i>E. mivati</i>; *2: also growth promotion and feed efficiency, improved pigmentation; limitations (Coyden 25/3-Nitro): feed up to 16 weeks of age if intended for use as caged layers, feed continuously as the sole ration
Pyridinones Clopidol *1 (113.5/227 chicken broilers, replacements), clopidol/roxarsone *2 (113.5/45.4) Coyden 25/3-Nitro (Merial USA), Type A medicated Articles, WT: chickens 5 days	1* Lerbeck 25, Coyden 25 (Merial USA; Type A medicated Articles, WT: 5 days, 1* Lerbeck Australia: oral powder WT: 0 day), limitations: do not feed to chickens over 16 weeks of age	First commercial use of drug products 1968; it arrests sporozoite and trophozoite development (= coccidiostatic effect: withdrawal of drug leads to relapse of infection); it is active against all <i>Eimeria</i> spp. in chickens but considerable problems have been reported with <i>E. acervulina</i>; drug resistance problems limit its use to shuttle programs (e.g., last 1–3 weeks of broiler grow-out); it is synergistic when combined with chemically related 4-hydroxy-quinolines; it is very safe for chickens and safe in mammals; approved indications: as an aid in prevention of coccidiosis caused by <i>E. tenella</i>, <i>E. necatrix</i>, <i>E. acervulina</i>, <i>E. maxima</i>, <i>E. brunetti</i>, and <i>E. mivati</i>; *2: also growth promotion and feed efficiency, improved pigmentation; limitations (Coyden 25/3-Nitro): feed up to 16 weeks of age if intended for use as caged layers, feed continuously as the sole ration

(continued)

Coccidiocidal Drugs, Table 1 (continued)

Chemical group nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*Brand names (manufacturer, companies, distributors), WT, other information	Comments on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
4-Hydroxyquinolines		
decoquinolate	I*Deccox (Alpharma USA, Germany, and elsewhere), Type A medicated Article for chickens (broilers) <i>limitations</i> : chickens not laying eggs, cattle (not lactating), young sheep and goats (not lactating)	First commercial use: buquinolate 1967 (withdrawn), decoquinolate 1970, methylbenzoate/clopidol 1974 (withdrawn); <i>buquinolate</i> was "commercially dead" within 6 months (sudden and dramatic appearance of drug resistance); hydroxyquinolines are almost entirely coccidiostatic against sporozoites and trophozoites of all <i>Eimeria</i> spp. in chickens (cf. clopidol; as single compounds they had only limited success: methylbenzoate (10 ppm and higher concentrations) proved ineffective against relevant <i>Eimeria</i> spp. due to serious and immediate development of drug resistance in the field; mode of action : hydroxy-quinolines target on energy metabolism: compounds block electron transport down the cytochrome chain in the mitochondria of coccidia and hence inhibit NADH oxidation and ATP synthesis as well; *1 <i>approved indications (chickens)</i> : for prevention of coccidiosis caused by <i>E. tenella</i> , <i>E. necatrix</i> , <i>E. acervulina</i> , <i>E. maxima</i> , <i>E. brunetti</i> , and <i>E. mivati</i> (*3-Nitro/Deccox: also growth promotion and feed efficiency, improved pigmentation); *1 (<i>cattle</i>): for prevention of coccidiosis in ruminating and nonruminating calves and cattle caused by <i>E. bovis</i> and <i>E. zuernii</i> ; (<i>goats</i>): for prevention of coccidiosis caused by <i>E. christenseni</i> and <i>E. ninakohlyakimovae</i> ; (<i>sheep</i>): for prevention of coccidiosis caused by <i>E. ovinoidalis</i> , <i>E. crandallis</i> , <i>E. parva</i> , <i>E. bakusensis</i> ; <i>general limitations</i> : bentonite should not be used in decoquinolate feeds, and other limitations for use in ruminants concerning dosage regimens (cf. label) in various feed and duration of prophylactic treatment (feed at least 28 days during periods of exposure to coccidiosis or when it is likely to be a hazard)
Nitrobenzamides		
Dinitolmide (125, chicken broilers, pullets, turkeys), not to be fed on laying hens; drug products available in <i>Australia</i> , elsewhere	*CCD D.O.T.: CCD AH and Nutrition (Ridley AG), *DOT 125 Premix: (Provimi Australia), oral powder, premix, WT: 0 day chicken (broilers, pullets) and turkeys	First commercial use: dinitolmide 1960, nitromide 1958 (withdrawn in the USA and elsewhere), aldomide 1965; drug arrests development of first- and second-generation schizonts and does not interfere with development of immunity; it is active against <i>Eimeria tenella</i> and <i>E. necatrix</i> but its effect against <i>E. acervulina</i> is limited; drug was combined with sulfanilic acid or roxarsone to enhance coccidiostatic activity and growth promotion; it may chiefly be used in breeder or replacement chickens (up to 14 weeks of age); mode of action is unknown; limitations : do not use in laying hens (chicken, turkeys)

*1 nitromide/sulfanitran (227/227 chickens), *2 nitromide/sulfanitran/roxarsone (227/227/45.4 chicken) *1 aklomide/sulfanitran (227/181 chickens) *2 aklomide/sulfanitran/roxarsone (227/181/45.4 chicken)	1*Unistat 2; 2*Unistat 3 (Fort Dodge USA, elsewhere), Type A medicated feed, medicated feed WT: 5 days 1*Novostat, 2*Novostat-3 Type A medicated Article, Premix, others (all Fort Dodge USA)	Is not currently marketed as a single agent; it was the first nitrobenzamide on the market and has same similar action on coccidia like dinitolmide; it may be used in breeders, broilers, and roasters; approved indications: as an aid in prevention of coccidiosis caused by <i>E. tenella</i>, <i>E. necatrix</i>, and <i>E. acervulina</i> (*2); also growth promotion and feed efficiency and improved pigmentation); limitations: not to be fed to laying chickens, and (*2) feed as a sole source of organic arsenic drug products can be used in breeders, broilers, and roasters and have similar activity against coccidia like dinitolmide and nitromide; approved indications and limitations (not to be fed to laying chickens, and (*2) feed as a sole source of organic arsenic) cf. nitromide†
Organic arsenicals		
Roxarsone 1*(45.4 chicken, turkeys) Arsanilic acid (90 chicken, turkey) Pro-Gen Plus Supplement (Fleming Labs, others, USA)	1*A.L. 3-Nitro (OZ-Biopharm, Alpharma, Australia) powder WT: chicken, turkeys 5 days; 2*/13 Nitro/BMD/Monteban (Alpharma USA)	First commercial use of roxarsone 1946, and arsanilic acid 1949; primary indication of arsenicals like arsanilic acid, or roxarsone (3-nitro-4-hydroxyphenyl-arsonic acid) is growth promotion; approved indication (1*A.L. 3-Nitro Australia, or *Zoco or *Zuco Tablets for Poultry, Alpharma, USA, oral liquid, WT: chicken, turkey 5 days): for growth promotion and improved feed conversion efficiency in chickens and turkeys; limitations: do not use in birds which are producing or may in the future produce eggs or egg products for human consumption, do not use in ducks, geese, or dogs nor for any other purpose or in any manner contrary to the directions on this label, feed as a sole source of organic arsenic; roxarsone has been reported to have some activity against <i>E. tenella</i> and <i>E. brunetti</i> (as a single agent or in combination with nitrobenzamides); in the European Union arsenicals have been prohibited and withdrawn from market; roxarsone is also used in combination with other agents as narasin, antibiotics (e.g., bacitracin methylene disalicylate, □ cf. 2*/13 Nitro/BMD/Monteban, Alpharma USA)

Coccidiocidal Drugs, Table 1 (continued)

Chemical group nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*Brand names (manufacturer, companies, distributors), WT, other information	Comments on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
Carbanilide derivatives		
Nicarbazin (113.5–125 chicken, breeders, broilers, roasters)	*Nicarbazin (Phibro AH, USA), Type A Medicated Article, WT: 4 days	Nicarbazin (introduced in 1955) was the first agent with “broad-spectrum” activity against <i>Eimeria</i> spp. of chickens; it is an equimolar complex of dinitrocarbanilide and dimethylpyrimidinol and still used as a single agent in the USA, Australia, elsewhere or in combination with polyether antibiotics (narasin, or maduramicin), roxarsone, or antibiotics (lincomycin, bacitracin, flavomycin in the USA, incl. roxarsone) for prevention and control of coccidiosis caused by <i>Eimeria</i> spp. (all relevant species) in broiler chickens; it shows synergistic effect with polyether antibiotics (cf. combination with narasin *Maxiban or maduramicin *Gromax); its action is primarily directed against developing second-generation <i>Eimeria</i> schizonts; it has approval for chickens only and may still be used in shuttle programs as starter feed preferably in winter or cooler months; this may be the reason why nicarbazin-resistant coccidia strains do not occur so frequently in poultry industry; however, there may be problems with side effects occurring during summer; it can cause increased sensitivity to heat stress, which may result in growth depression and even mortality in broilers; death may be due to cell degeneration processes in liver and kidneys; at recommended dose, the drug causes occasionally toxic effects in laying hens like reduced hatchability and interruption of egg laying; mode of action is not yet well understood and potential targets of selective toxicity in coccidia are unknown; approved indications (USA): aid in preventing outbreaks of cecal (<i>E. tenella</i>) and intestinal (<i>E. acervulina</i> , <i>E. maxima</i> , <i>E. necatrix</i> , and <i>E. brunetti</i>) coccidiosis; limitations : feed continuously as sole ration from time chicks are placed on litter until past the time when coccidiosis is ordinarily a hazard, do not use as a treatment for coccidiosis, do not use in flushing fashers
Thiamine analogues	*Amprolimum: various products for prevention and treatment (Merial USA)	Amprolimum (introduced 1960) is structurally related to the vitamin thiamine and is soluble in water as HCl salt; its activity is primarily directed against first-generation schizonts of <i>Eimeria</i> spp. (prevents development of merozoites and thus reduces production of second-generation schizonts); there is some activity against gamonts (sexual stages); it may affect sporulation process in the oocyst (development of sporozoites); it is coccidiostatic at lower, and coccidiocidal at higher doses and is a very safe agent in poultry and mammals; APL-resistant <i>Eimeria</i> strains are prevalent in broiler chickens and floor-reared replacement pullets or turkeys, which limits its use in the field; APL is combined with other agents (e.g., <i>ethapabate</i> or
Amprolimum (APL)	1*Type A medicated Article, poultry WT: 0 day, cattle, calves 1 day; or 9.6 % solutions or 20 % soluble powder (WT see above) for the treatment (amount see label)	
*1 (36.3–113.5, chicken broilers, replacements)	2*Amprolimum 200 Soluble Powder (200 g/kg APL HCl) (Australia), oral powder (drinking water), WT: 0 day;	
*1 (113.5–227, chicken laying, 227: treatment)		
*1 (113.5–227 turkeys)		
*1 (159 pheasants growing), *1 (5 mg/kg b.w. cattle for 21 day)		

*2 amprolium HCl (240 mg/L for 24 h every fourth day as long as infection is likely: chickens, turkeys, ducks, pigeons) *3 amprolium/ethopabate (125/8, chicken, turkey) *4 amprolium/ethopabate/roxarsone (113.5/3.6/45.4 chicken broilers)	3*Keymix Keystat Powder Feed Additive (Internat. AH Products) 3* Amprolmix Plus (Merial Australia), oral powder, premix in feed, WT: 0 day 4* Broiler PMX No.1620 (Merial USA), Type A medicated Article, WT: broiler 5 days	<i>roxarsone</i>) to enhance anticoccidial activity; approved indications (USA): APL and combinations (APL/ethopabate; APL/ethopabate/roxarsone: available as feed additives or other dose forms) may be used in poultry (chicken broilers, broiler breeders, or replacement pullets: latter feed from day-old till 6–8 weeks of age), (guinea fowl), turkeys (poult: from day-old till 6–8 weeks of age), ducks and pigeons for the treatment and an aid in the prevention of coccidiosis caused by <i>Eimeria tenella</i>, <i>E. acervulina</i> (most strains are affected), <i>E. maxima</i> (affected to a lesser degree), <i>E. necatrix</i>, and <i>E. brunetti</i>, pathogen <i>Eimeria</i> spp. of turkeys and other species of ducks and pigeons (*4); in addition, growth promotion and feed efficiency, improved pigmentation); drug products may be used in turkey poult because of its good tolerability and encouraging immunity to develop, needed for satisfactory performance of replacement pullets and poult following withdrawal of agent; in <i>cattle</i> and <i>calves</i> *Amprovine is used as an aid in the treatment of coccidiosis caused by <i>E. bovis</i> and <i>E. zurnii</i>; mode of action: in parasites, APL competitively inhibits uptake and active transport of thiamine (coccidia may be 50-fold more sensitive to the system than that of the host); thiamine pyrophosphate is a cofactor of several enzymes involved in decarboxylating processes playing a role in cofactor synthesis; APL cannot be pyrophosphorylated (lacks hydroxyethyl group); limitations (*3, *4): do not use in birds, which are producing or may in the future produce eggs or egg products for human consumption; (*4): feed as a sole source of organic arsenic
	Quinazolinones Halofuginone (introduced 1976) was originally derived from a plant extract (<i>Dichroa febrifuga</i> Lour); isolated febrifugine had an antimalarial and anticoccidial effect but a too narrow safety margin; structural variations of the alkaloid (previously performed by American Cyanamid) led to halofuginone; its mode of action is unknown; the alkaloid is <i>toxic to fish</i> and other aquatic species Halofuginone Hydrobromide (HAL) *1 (2–3 chickens EC) *1 (2.72 chicken broilers, replacement cage layers, and replacement broiler breeders, USA) *1 (1.36–2.72 turkeys growing, USA) Halofuginone/roxarsone *2 (2.72/22.7–45.4 chicken replacement broilers not over 20 weeks age, chicken, replacements for caged layers not over 16 weeks)	

(continued)

Coccidiocidal Drugs, Table 1 (continued)

Chemical group nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*Brand names (manufacturer, companies, distributors), WT, other information	Comments on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
		feed continuously as sole ration, withdraw 4 days before slaughter, do not feed to layers); limitations (replacement cage layers and replacement broiler breeder): feed continuously as sole ration to replacement cage laying chickens until 20 weeks of age, feed continuously as sole ration to replacement broiler breeder chickens until 16 weeks of age, withdraw 4 days before slaughter, do not feed to laying chickens or water fowl; approved indications (turkey growing USA): for prevention of coccidiosis in growing turkeys caused by <i>E. adenoeides</i>, <i>E. meleagris</i>, and <i>E. gallopavonis</i>; limitations: feed continuously as sole ration, withdraw 7 days before slaughter, do not feed to layers or water fowl; approved indications (chicken) 2*/3-Nitro/Stenorol, cf. 2*): for prevention of coccidiosis caused by <i>E. tenella</i>, <i>E. necatrix</i>, <i>E. acervulina</i>, <i>E. brunetti</i>, <i>E. mivati</i>, and <i>E. maxima</i>, for increased rate of weight gain, improved feed efficiency, and improved pigmentation; limitations: feed continuously as sole ration to replacement cage laying chickens until 20 weeks of age, and to replacement broiler breeder chickens until 16 weeks of age, use as the sole source of organic arsenic; drug overdose or lack of water intake may result in leg weakness or paralysis, do not feed to laying chickens or waterfowl; general limitations: avoid contact with skin, eyes, or clothing, do not contaminate dams, rivers, streams, or other waterways with the chemical; tolerability and metabolism: at recommended dose, HAL is well-tolerated in chicken and turkeys; however, it is unpalatable at the recommended feed concentrations for anseriformes (ducks, geese, swans), water fowl, guinea fowls, partridges, or other game birds and rabbits; if fed continuously there is a drastic reduction in feed intake followed by serious toxic reactions and occasionally mortality; other adverse effects may be associated with skin tears in chicken (HAL is an inhibitor of collagen type I synthesis in avian and mammalian fibroblasts thereby decreasing skin strength and increasing incidences of skin tears during processing); however, in shuttle programs, in which halofuginone is included in grower feed, it seems to maintain skin integrity in broilers; in toxicity studies on laying hens it was shown that HAL is transmitted to eggs (there were no adverse effects on egg production or egg quality); it irritates skin and eyes after contact (precaution should be taken during handling this agent)

Guanidine derivatives

Robenidine (introduced 1972) is a synthetic anticoccidiocidal derivative of guanidine; if not withdrawn 5 days before slaughter or used at higher than the recommended dose edible tissues and eggs of layers of medicated birds will have an unpleasant (medical) taste; mode of action of robenidine is believed to interfere with energy metabolism by inhibition of respiratory chain phosphorylation and ATPase activity in rat liver mitochondria; however, other guanidine derivatives lacking anticoccidiocidal activity also share this inhibitory activity on oxidative phosphorylation process

Robenidine hydrochloride	*1 (30–36 chicken broilers, fryers; EC; and turkeys growing)	Has broad anticoccidiocidal spectrum of activity including <i>Eimeria</i> spp. of birds and mammals (EC approval for rabbits at 50–66 ppm for prevention of coccidiosis caused by intestinal <i>Eimeria</i> spp. only); it affects late developing stages of first- and second-generation schizonts; it may have some activity against gamonts (sexual stages); its action is both first coccidiostatic and then coccidiocidal; <i>Eimeria</i> spp. may easily and quickly develop resistance to the agent; there were reports of unexpected outbreaks of drug resistance in the USA and Canada within a year of its introduction in poultry farms; approved indications (USA): an aid in prevention of coccidiosis caused by <i>E. mivati</i> , <i>E. brunetti</i> , <i>E. tenella</i> , <i>E. acervulina</i> , <i>E. maxima</i> , and <i>E. necatrix</i> (EC: in addition <i>Eimeria</i> spp. of turkeys such as <i>E. adenocoides</i> , <i>E. meleagris</i> , and <i>E. gallopavonis</i>); limitations : do not feed to layers, feed continuously as the sole ration, Type C feed containing robenidine HCl must be fed within 50 days from the date of manufacture, do not use in Type B or Type C medicated feeds containing bentonite; 2*Robenz Plus: in addition: feed as a sole source of organic arsenic
Robenidine/roxarsone	1*Cycostat 66G (Alpharma Australia; EC) for broiler chickens (Australia) and growing turkeys (up to 12 weeks of age) and rabbits (EC) 1*Robenz (Alpharma USA) for chickens (broiler and fryers): 1*/2*: all Type A medicated articles (WT: all 5 days)	

Polyether ionophorous antibiotics (discovered in the early 1950s and anticoccidiocidal activity recognized in late 1960s) are fermentation products of various *Streptomyces* spp. or *Actinomadura* sp. (maduramicin, semduramicin) containing mycelial biomass (maduramicin can be extracted into granular carrier); ionophores have different affinities to different cations; their mode of action is related to their ability to interact with physiologically important monovalent and divalent cations (e.g., Rb⁺, Na⁺, K⁺, Cs⁺, or Ca²⁺) to form lipophilic complexes and transport so cations across biological membranes thereby destroying their cross-membrane gradients; sporozoites of *E. tenella* are killed after 12–24 h-incubation in “solutions” of monensin, salinomycin and lasalocid, respectively, at very low concentrations (Raether et al. 1991); ionophores also altered irreversible free *Eimeria tenella* merozoites and mature (first- and second- generation) schizonts or erythrocytic stages of various chloroquine-resistant strains of *Plasmodium berghei* in vitro; *Eimeria*-infected chickens fed with polyether antibiotic-medicated feed show usually relatively high oocyst outputs in feces; this may be due to ionophores’ lack of activity against sporozoites in vivo; broad-spectrum activity of polyether antibiotics against all pathogenic *Eimeria* spp. in poultry gave them continuing commercial success till mid- to late 1980s as first (Raether et al. 1991); ionophore-resistant strains of chicken *Eimeria* spp. were documented in Europe, USA, and elsewhere; today, ionophore resistance is common though response of resistant strains to specific ionophores may be different; there may be side resistance between monovalent ionophores (e.g., salinomycin/monensin) or cross-resistance between monovalent and divalent ionophores (e.g., monensin/lasalocid); in general, side-resistance among monovalent ionophores is widespread because this group of compounds is frequent used in the poultry industry; however, *Eimeria* spp. of poultry will retain their susceptibility to monovalent and divalent polyether antibiotics if concerned drug products are used strategically in the field (e.g., rotation programs); ionophores are potential toxic for highly susceptible animals such as horses and other equines, their safety margin is narrow in birds and mammals; concurrent use of tiamulin (a macrolide antibiotic) and certain anticoccidiocidal ionophores produces adverse effects in poultry, such as weight depression and mortality due to retarded elimination of the ionophores via feces; lasalocid, maduramicin, and semduramicin are compatible with tiamulin but most of the ionophores may interact with sulfonamides and erythromycin; dose-related toxicity is evident by weakness, leg paralysis, and sharp reduction of water intake; anticoccidiocidal ionophores may be used as feed additives for preventing coccidiosis in poultry (rabbits; EC?; ruminants; USA, Australia, elsewhere) or as feed additives for improving feed conversion efficiency and/or weight gain in cattle or swine in the USA and elsewhere (an EU-wide ban on antibiotics as growth promoters in animal feed entered into effect on January 1, 2006; Commission Regulation, EC No. 600/2005, April 2005 concerning a new authorization for 10 years of a coccidiostatic as an additive in feedstuffs including certain polyether antibiotics, see also below)

(continued)

Coccidiocidal Drugs, Table 1 (continued)

Chemical group nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*Brand names (manufacturer, companies, distributors), WT, other information	Comments on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
Monensin-Na (sodium) (MON) USA: (90–110 chicken broilers, replacements) (54–90 turkeys, no use class stated or implied) (73 Bobwhite quails, growing) Australia: (100–120 chicken broilers, replacements) EC (100–125 chicken broilers), (100–120 chicken replacements) (60–100 turkeys growing)	*Coban; *Elanco AH, Eli Lilly USA, Australia, EC), Type A medicated articles, others, WT: USA and Australia 0 day, EC 3 days, other drug products (in the USA: roxarsone or antibiotics combined with MON); general limitations: do not feed to laying chickens, do not allow horses, other equines, mature turkeys, or guinea fowl access to feed containing MON	Fermentation product of <i>Streptomyces cinnamonensis</i> (introduced in 1968); MON was the first ionophore used in poultry industry; approved indications (USA, elsewhere): as an aid in prevention of coccidiosis in chickens caused by <i>E. necatrix</i>, <i>E. tenella</i>, <i>E. acervulina</i>, <i>E. brunetti</i>, <i>E. mivati</i>, and <i>E. maxima</i>; limitations: in growing bobwhite quail: <i>Eimeria dispersa</i> and <i>E. leytiae</i>; limitations: feed continuously as sole ration as MON sodium, do not feed to chickens (and turkeys: EC) over 16 weeks of age; chicken broilers: in the absence of coccidiosis, the use of MON sodium with no withdrawal period may limit feed intake resulting in reduced weight gain; feed continuously as the sole ration to growing turkeys from 1 day of age as MON sodium; tolerability: MON may produce poor feathering when feeding diets with low energy and low sulphur-containing amino acids; tiamulin interferes with metabolism of MON in chickens; at recommended doses MON may be toxic to guinea fowl and other avian species; horses are very sensitive to MON (LD 50 %: horse 2–3 mg/kg b.w., cattle 25 mg/kg; chickens 200 mg/kg); contraindication MON will cause deaths in equines that ingest feed containing it
Lasalocid-A-Na (sodium) (LAS) USA (68–113 chicken broilers, fryers, turkeys growing), (113 Chukar partridges) EC (75–125 chicken broilers, replacements up to 16 weeks of age) (90–125 turkeys up to 12 weeks of age) Australia (75–100 chicken broilers, rearing replacement pullets, turkeys)	*Avatec (Alpharma EC, USA, Australia), Type A Medicated Article, others (medicated feed), WT: USA, Australia 0 day, EC 5 days; other drug products (in the USA: roxarsone or antibiotics combined with LAS) limitations: feed continuously as the sole ration, not to be added to feed consumed by hens producing fertile eggs or by game birds other than turkeys and Chukar partridges;	Fermentation product of <i>Streptomyces lasaliensis</i> (introduced in 1974); it structurally differs from other ionophores and has strong affinity to <i>divalent</i> cations; metabolism of LAS appears to differ from that of monovalent ionophores, for its usage is associated with wet litter at the higher dosage levels and it is well tolerated when fed with tiamulin; at 75 ppm its activity against <i>E. acervulina</i> is unsatisfactory but good against <i>E. tenella</i>; <i>E. tenella</i> strains resistant to monovalent ionophores may be controlled with LAS; in the USA (elsewhere), LAS is approved for the prevention and control of coccidiosis caused by various <i>Eimeria</i> spp. of cattle (excluding veal calves), sheep and young domestic rabbit (only <i>E. stiedae</i>); it shows efficacy against <i>Eimeria</i> spp. of sheep, cattle, and domestic rabbits (<i>E. stiedae</i>) may be used in the USA (e.g., *Bovatec, or *Avatec, others, various oral drug forms, cattle and sheep: also for improved feed efficiency and increased rate of weight gain: approved indications in birds (*Avatec, USA, elsewhere): for prevention of coccidiosis in chickens (broilers, fryers) caused by <i>E. necatrix</i>, <i>E. tenella</i>, <i>E. acervulina</i>, <i>E. brunetti</i>, <i>E. mivati</i>, and <i>E. maxima</i>; in turkeys (growing) <i>E. adenoeides</i>, <i>E. meleagridis</i>, and <i>E. gallopavonis</i>; and in Chukar partridges (up to 8 weeks of age) <i>E. legionensis</i>; contraindications: not to be fed to horses or other equid species

Salinomycin-Na (sodium) (SAL) USA (40–60 chicken broilers, roasters, replacements, excluding layers), (50 quail, no use class stated or implied) EC (60–70 chicken broilers), (50: up to 12 weeks age replacements) Australia (60 chicken broilers, replacements, excluding layers)	*Bio-Cox (Alphaarma USA, Australia) Type A Medicated Article, others (medicated feed), WT: USA, Australia 0 day; other drug products (in USA: roxarsone or antibiotics combined with SAL) *Sacox 120; Intervet EC), Type A Medicated Article (medicated feed), WT: EC 5 days; other drug products	Fermentation product of <i>Streptomyces albus</i> (introduced 1978); SAL is active against all pathogen <i>Eimeria</i> spp. of poultry and affects particularly developmental stages in the early and late phase of coccidia life cycle as sporozoites and late asexual stages (second/third schizont-generation). SAL has been reported to have a pronounced effect against <i>E. tenella</i> and <i>E. acervulina</i> (including against drug-resistant <i>Eimeria</i> spp. in the field); SAL is active against coccidia of the domestic rabbit (approval by EC: e.g., *Sacox 120: 20–25 ppm); tolerability: at recommended dose, SAL is toxic for turkeys (particularly in adult birds: growth depression, excitement followed by paralysis with head and legs extended, mortality), horses, and other equines; <i>tiamulin</i> interferes with metabolism of SAL in chickens and causes weight depression; approved indications in birds (*Bio-Cox, *Sacox, others): for prevention of coccidiosis in chickens (broilers, roasters, replacements) caused by <i>E. necatrix</i>, <i>E. tenella</i>, <i>E. acervulina</i>, <i>E. brunetti</i>, <i>E. mitis</i>, (<i>E. mivati</i>), and <i>E. maxima</i>; and in quail: <i>E. dispersa</i> and <i>E. lettyae</i>; approved indication as <i>growth promoter</i> (Australia, elsewhere): for improvement of productivity by stimulating the growth rate and increasing feed conversion of grower (30–60 ppm)/finisher (15–30 ppm) pigs and feedlot beef cattle (15 ppm), do not use in cows, which are producing, or may in the future produce milk or milk products for human consumption; limitations (USA, elsewhere): feed continuously as sole ration, do not feed to laying hens producing eggs for human consumption, not approved for use with pellet binders, may be fatal if accidentally fed to horses or adult turkeys
Narasin (approval for broiler chickens only) *1•USA (54–72) *1•EC (60–70) *1•Australia (60–80) Narasin/nicarbazin (1:1) (total active ingredient) *2•USA (54–90) *2•EC, Australia (80–100) (in the USA: roxarsone or antibiotics combined with narasin or narasin/nicarbazin)	1*Monteban (Elanco AH; Eli Lilly, USA, Australia, EC) Type A Medicated Article, others (medicated feed), WT: USA, Australia 0 day; EC 5 days 2*Maxiban (Elanco AH; Eli Lilly, USA, Australia, EC) Type A Medicated Article, others WT: USA, EC 5 days, Australia 0 day	Fermentation product of <i>Streptomyces aureofaciens</i> (introduced 1983) and closely related in its structure to salinomycin but not as active as this; to enhance activity, narasin has been combined with synergistic acting nicarbazin (2*Maxiban, introduced 1988); the combination may be used in starter phase of shuttle programs followed by a different ionophore in grower-finisher phase; 1*2* approved indications: for prevention of coccidiosis in chickens (broilers only) caused by <i>E. necatrix</i>, <i>E. tenella</i>, <i>E. acervulina</i>, <i>E. brunetti</i>, <i>E. mitis</i>, (<i>E. mivati</i>), and <i>E. maxima</i>; approved indication as <i>growth promoter</i> (Australia, elsewhere): for improved feed conversion efficiency in lot-fed cattle (approved: 5–13 ppm), 1*2* limitations: feed continuously as the sole ration, do not feed to laying hens, do not use in laying hens, turkeys, or game birds, nor in horses or other equines (may be fatal), poultry consuming narasin should not be treated with <i>tiamulin</i> (severe growth depression or death may occur)

(continued)

Coccidiocidal Drugs, Table 1 (continued)

Chemical group nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*Brand names (manufacturer, companies, distributors), WT, other information	Comments on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
Maduramicin ammonium (MAD)	*Cygro (Alpha USA, Australia, EC) Type A Medicated Article, others (medicated feed), WT: USA, EC 5 days, Australia 0 day; limitations: feed continuously as sole ration, do not use in birds which are producing or may in the future produce eggs or egg products for human consumption	Fermentation product of <i>Actinomadura yumaense</i> (introduced 1984), having a sugar moiety as side chain (monoglycoside polyether); it has affinity to both monovalent and divalent cations and shows at very low dose levels a good activity against all pathogenic <i>Eimeria</i> spp. of chickens; cross-resistance with other polyether antibiotics has been reported soon after its introduction in the poultry industry and *Gromax (MAD/nicarbazin, introduced 1992) increased anticoccidial activity; limitation: for the prevention of coccidiosis in broiler chicken; medicated feed containing *Gromax should be fed continuously to broiler chickens as the only ration; MAD is not as toxic as other ionophores for birds and mammals (not approved species like turkeys, guinea fowl, pheasants, geese, ducks, cattle, sheep, horses, pigs, or rabbits tolerate it at recommended dose level); it is well tolerated when fed with tiamulin; approved indications for *Cygro (<i>Eimeria</i> spp. of chickens and turkeys cf. lasalocid)
MAD/nicarbazin (3.75/40 chicken broilers) limitation: do not use in birds, which are producing or may in future produce eggs or egg products for human consumption	*Gromax (Alpha Inc. Australia) oral powder, Premix, WT 1 day	
Senduramicin Na (sodium) (SEM) approval for broiler chickens only	*Aviax (Phibro AH; USA, Australia, EC), Type A Medicated Article, others (medicated feed), WT: USA, Australia 0 day, EC 5 days; other drug products (in USA: roxarsone or antibiotics combined with SEM, all WT 5 days); do not feed to laying hens	Fermentation product of a mutant of <i>Actinomadura roseorufa</i> (introduced 1991, latest ionophore on the market) developed as feed additive for the prevention of coccidiosis in broiler chickens; it is a monovalent monoglycoside polyether ionophore (parent strain produced a diglycoside form of SEM; this can be semi-synthetically modified to obtain the monoglycoside; both forms have identical anticoccidial activity); it is active against all pathogenic <i>Eimeria</i> spp. of chickens with pronounced efficacy against <i>E. maxima</i> ; cross-resistance with other polyether antibiotics has been reported in Europe, South America, and the USA soon after its introduction in the poultry industry; concurrent use of tiamulin and SEM is well tolerated; approved indications (USA): for prevention of coccidiosis caused by <i>E. tenella</i> , <i>E. acervulina</i> , <i>E. maxima</i> , <i>E. brunetti</i> , <i>E. necatrix</i> , and <i>E. mitis</i> ; *Nitro/Aviax: including some field strains of <i>E. tenella</i> that are more susceptible to SEM combined with roxarsone than SEM alone; general limitations: feed continuously as sole ration, do not use in birds which are producing or may in the future produce eggs or egg products for human consumption
SEM/roxarsone (22.7/45.4) *Nitro/Aviax WT: 5 days use as sole source of organic arsenic		

Asymmetric (1,2,4) triazines in the early 1980s there have been several 1,2,4-triazine derivatives under development, e.g., <i>clazuril</i> and <i>diclazuril</i> (US patent application to Janssen 1984) and HOE 092 V (DE patent application to Hoechst AG, 1985, drug development as a feed additive was discontinued during preclinical studies; there were adverse effects on endocrine system in rodents and feathering in chickens); HOE 092 V proved to be highly active against all pathogenic <i>Eimeria</i> spp. of chickens, turkeys, and rabbits; it had also an excellent effect against various pathogen protozoa and crustacean parasites of fish including a variety of gill- and skin-parasitizing monogeneans; thus a single medical bath (10 µg HOE 092 V/ml for 4 h) was sufficient to kill trophozoites of <i>Lchthyophthirius multifiliis</i>; at higher dose levels also <i>toltrazuril</i> is active against various fish parasites; it belongs to the symmetric (1,3,5) triazines (cf. <i>toltrazuril</i> (below) and may be used as a therapeutic drug against coccidiosis of birds and mammals, e.g., swine)	
Didlazuril (DZU)	Synthetic agent (introduced 1988), chemically a benzeneacetoneitrile derivative with high anticoccidial activity when fed at low levels in feed; it has a strong anticoccidial activity against developing first- and second-generation schizonts, and gamonts of <i>E. tenella</i> and other pathogenic <i>Eimeria</i> spp. of chickens but developmental stages most affected by DZU varies with the <i>Eimeria</i> spp.; it is highly effective against <i>E. tenella</i> (all stages) but not so against <i>E. maxima</i> (gamonts only); because it is effective against this species later in its life cycle, subclinical intestinal lesions may be present for a short time after infection; nevertheless, DZU was shown in studies to reduce lesion scores and improve performance and health of birds challenged with <i>E. maxima</i>; when used for longer periods in straight programs, coccidia of chickens may develop resistance to the drug; for that reason it may be frequently used in shuttle programs; complete cross-resistance with <i>toltrazuril</i> may be evident in the field; DZU may be useful in the treatment of hepatic and intestinal coccidiosis of the domestic rabbit (currently not approved indication); approved indications (EC, USA, elsewhere): for prevention of coccidiosis caused by <i>E. tenella</i>, <i>E. necatrix</i>, <i>E. acervulina</i>, <i>E. brunetti</i>, <i>E. mitis</i> (<i>minvati</i>), and <i>E. maxima</i> in chicken, and <i>E. adenoeides</i>, <i>E. gallopavonis</i>, and <i>E. meleagrinis</i>, for increased rate of weight gain and improved feed efficiency in turkeys; it appears to be compatible with other feed additives and is a very safe drug in various animals (chicken broiler, breeder, turkey, guinea fowl, quail, duck, mouse, rat, rabbit, dog, piglet, horse, cattle, sheep, and goat); limitations: chicken feed continuously, not for use in hens producing eggs for human food; turkeys feed continuously as the sole ration, do not feed to breeding turkeys, not for use in hens producing eggs for human consumption
USA (0.91/1 ppm chicken, broilers not laying eggs for human consumption), (0.91 in combination with bacitracin methylene disalicylate 4–50 g/ton of feed: turkey, growing, not laying eggs for human consumption) EC (1 chicken broilers, replacements up to 16 weeks of age, turkeys, growing up to 12 weeks of age)	*Clinacox (Schering-Plough AH, USA, Janssen AH EC) (not commercially available in Australia), Type A medicated article (medicated feed), WT: USA 0 day, EC 5 days *Vecoxan (Janssen-Cilag, Germany, elsewhere) for calves (5 months of age), lambs, oral suspension (2.5 mg/ml), WT: 0 day (single dose: 1 mgDZU/kg b.w.) for prevention of coccidiosis
Clazuril (5 mg/kg b.w., minimum, carrier pigeons only) not for use in pigeons producing eggs for human consumption	*Appertex (Janssen-Cilag, Germany, elsewhere), oral tablets (2.5 mg clazuril/tablet)

(continued)

Coccidiocidal Drugs, Table 1 (continued)

Chemical group nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*Brand names (manufacturer, companies, distributors), WT, other information	Comments on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
Symmetric (1,3,5) triazines		
Toltrazuril (TZU, *Baycox Bayer, Australia, Germany, elsewhere, introduced 1987) differs from diclazuril (an asymmetric 1,2,4 triazine above) principally in its pharmacokinetic properties (different biotransformation and excretion processes result in a long elimination half-life of TZU and consequently in long withdrawal periods before slaughter); thus TZU is not suitable to be fed continuously as a sole ration in poultry, other birds, and mammals; it is active against both developing first- and second-generation schizonts and gamonts of pathogenic <i>Eimeria</i> spp. of birds (e.g., chicken, geese, ducks and others) and mammals (e.g., cattle, sheep, goats, pigs, rabbits, and others); TZU inhibits nuclear division of schizonts and microgamonts and the wall-forming bodies of macrogamonts; because of similar mode of action of symmetric and asymmetric triazines there is cross-resistance between toltrazuril and diclazuril; intermittent administration of TZU via drinking water may help to establish efficient metaphylactic programs against coccidiosis in chickens and turkeys thereby allowing development of protective immunity; TZU may be used for the control of coccidiosis in neonatal piglets caused by <i>Isoospora suis</i> (*Baycox Piglet Coccidiocide, Australia, oral liquid: 50 g TZU/L; 1 mL/3–6 day-old piglet once, WT: 70 day); *Baycox Bovis (50 mg/ml suspension, Bayer Vital Germany) can be used (15 mg/kg b.w. × 1, per os) to prevent coccidiosis in calves up to 5 months of age (WT 63 days); moreover it has a broad-spectrum antiprotozoal activity against <i>Sarcocystis</i> spp., <i>Toxoplasma gondii</i> , <i>Cystoisospora</i> spp., and <i>Hepatozoon</i> spp. of mammals; its activity is also directed against fish parasites such as microsporidia, myxozoa, and monogeneans, or <i>Nosema</i> apis of bees; TZU is very well tolerated in birds, mammals, and fish; approved dosage regimens in chickens (Australia, elsewhere) (*Baycox Coccidiocide Solution, 25 gTZU/L oral liquid, dose rate: 3 L/1000 L, WT: 14 days chickens) is intended for use in treatment programs (e.g., in case of a clinical outbreak of coccidiosis in chickens) and is given via drinking water in an 8-h treatment period each day for 2 days, if required, treatment may be repeated after 5 days; it can be also used in preventive coccidiosis programs on days 9 and 10, 16 and 17, and 23, and 24 of life; an additional administration may be necessary after 35 days but not within the 14 days withdrawal period of slaughter; approved dosage regimens (Germany, elsewhere): treatment of coccidiosis in chickens and turkeys via drinking water on two successive days continuously for 24 h/day (*Baycox 2.5 %, oral liquid, WT: chicken 21 day, turkeys 18 days; dose rate 1 mL/L drinking water = 25 ppm TZU), or as alternate: continuously for 8 h/day (*Baycox 2.5 %, oral liquid, dose rate 3 mL/L drinking water = 75 ppm TZU), minimum dose should be 7 mg/kg b.w./day; general limitations : eggs do not use TZU within 6 weeks prior to laying of eggs to be used for human consumption or processing, do not use in replacements over 15 weeks of age; law may restricts this drug use by or on the order of a licensed veterinarian; drug products containing TZU are not commercially available in the USA		
Authorization of feed additives as coccidiostats		
Only feed additives that were granted an authorization following a scientific evaluation for example by the US Food and Drug Administration (*FDA) Center for Veterinary Medicine (*CVM), the Australian Pesticides and Veterinary Medicines Authority (APVMA's), the European Food Safety Authority (EFSA), or other National Authorities will be put on the market. These authorities regulate the manufacture and distribution of approved feed additives (*and drugs) that will be given to animals. Concerning this table, approved feed additive products for target species (animals) listed as of year 2006/2007 (and possibly following years), are available on the market in all Member States of Europe, the USA, Australia, and elsewhere		
Currently, European Parliament and Council Regulation 1831/2003 (replacing Directive 70/524/EEC) regulate the use of additives in animal nutrition. It sets out rules for the authorization, marketing, and labelling of feed additives, including the category < coccidiostats and histomonostats > previously authorized under Regulation 70/524/EEC. Regulation 1831/2003 also completes the <i>ban on antibiotic growth promoters</i> (January 1, 2006) in feed by prohibiting the use of 4 antibiotic substances (monensin sodium, salinomycin sodium, avilamycin, and flavophospholipol). The EU has already banned antibiotics used in human medicine from being added to animal feed. The Commission's overall strategy is to tackle the emergence of bacteria and other microbes resistant to antibiotics, due to their overexploitation or misuse. Antibiotics will now only be allowed to be added to animal feed for veterinary purposes		
Commission Regulation (EC) No. 600/2005 (Annex I 'coccidiostats and other medicinal substances') laid down conditions for submission and application for a new authorization for 10 years of coccidiostats as additives in feeding stuffs. Most in-feed substances (at least one target species as broiler chicken, doses) listed in Table 1 are already authorized for 10 years (2014/2015), such as decoquinat (756), monensin sodium (E 757), robenidine hydrochloride (758), lasalocid-A-natrium (E 763), narasin (E 765), salinomycin sodium (E 766), or less than 10 years such as diclazuril (E 771: 2009–2013), halofuginone hydrobromide (E 764: pullets, 2009), narasin 80 g/kg-nicarbazin 80 g/kg (Maxiban G160) (E 772: 2009), maduramin-ammonium alpha 1 g/100 g (E 770: 2009/2011: broiler chicken/growing turkeys), and senduramin sodium (29): June 2006, withdrawn ?). Withdrawn authorization (Directive 70/524/EEC) of feed additives as coccidiostats entered into effect on 1999 for aprinocidine and dinitolmide (EC regulation 45/1999), and on 2001 for amprolium, amprolium/ethopabate, meticlorpindol, meticlorpindol/methylbenzoquate, and nicarbazin (EC regulation 22/05/2001)		
Data of drug products (approved labels) listed in this table refer to information from literature, manufacturer, supplier, and websites such as the European Medicines Agency (EMA), Committee for Veterinary Medicinal Products (CVMP), the US Food and Drug Administration (FDA), Center for Veterinary Medicine (CVM), the Australian Pesticides and Veterinary Medicines Authority (APVMA) and associated Infopest (search for products), VETIDATA, Leipzig, Germany, and Clini Pharm, Clini Tox (CPT), Zurich, Switzerland. Data given in this table have no claim to full information		

controlling coccidia infections with chemotherapy may be coccidiosis vaccines. As a result of public pressure against continuous medication, drug resistance problems, and the high cost of drug clearance vaccines, which are able to induce sufficient immunity (both humoral and cellular response) and thus provide flock protection against ► **morbidity** and ► **mortality**, would be an appropriate alternative.

Epizootiology and Control Measures

The application of any control methods, whether hygienic, chemotherapeutic, or immunological, needs profound knowledge of the ► **epizootiology** of various coccidiosis. The term coccidiosis is used to describe relatively nonpathogenic and usually mixed infections, whereas coccidiosis is a severe disease in the host. In papers related to human medicine the ending *iasis*, however, is used to indicate an acute phase of disease with severe clinical symptoms. Thus the parasitological literature may lead to confusion on the severity of the disease. Mixed infections, i.e., those where animals are infected with more than one species of coccidia, are very common and only some species are highly pathogenic. The severity of the disease is the result of the combined actions of the particular mixture of coccidia, the number of sporulated oocysts ingested with feed or water. However, it may be influenced also by the nutritional condition of the host, environmental and climatic factors (such as temperature, moisture, oxygen tension, and sunlight) and the management practices used. Crowding of animals due to intensive rearing, e.g., in the broiler industry where large numbers of chickens are kept in enormous houses, creates conditions favorable to sudden outbreaks of severe coccidiosis. Fecal debris may concentrate large numbers of oocysts, which can rapidly sporulate and become infective under warm and moist conditions. Severe coccidiosis is, therefore, mostly a “man-made” problem with domestic animals and is not a general problem in the wild or on pastures. When coccidiosis is suspected and oocysts are found, the species present should be identified. A periodic examination of feces for

oocysts and a postmortem examination in a few animals will give valuable information on the status of infection.

Coccidiosis cannot be recognized clinically until tissue damage associated with second- or third-generation ► **schizogony** occurs. When the disease is present, the **clinical signs** are catarrhalic or hemorrhagic enteritis. The severity of disease is often complicated by the presence of secondary bacterial infections. Moderately affected animals show poor weight gain or weight loss, weakness, and emaciation, severely affected animals (chiefly young ones) may die very soon after the first clinical signs are seen. Since coccidia have a self-limiting life cycle, the acute phase of infection may have already passed before therapeutic treatment can be started. Thus, **treatment** is usually too late to prevent economic loss. All classes of domestic animals can be affected by coccidia, and losses due to coccidiosis in mammals (particularly in bovines: cattle, sheep, goats, swine, and rabbits) are difficult to determine. The expenses of management practices and the cost of preventive or therapeutic drugs are the main points of consideration. Using suitable control measures can minimize symptoms of the disease. There should be **strict sanitation** to prevent feed and water being contaminated by feces, and feedlots, pens, cages, or hutches should be kept dry and well drained and be cleaned out regularly (preferably every day in rabbitries). When outbreaks occur in pasture, water holes and ditches should be fenced off. Crowding of young animals should be avoided.

Negative effects of intensive animal production are numerous. Thus manure/mineral (phosphate/nitrate) accumulation (used as fertilizer), ► **ammonia** emission, (one of main causes for acid rain), dead animal disposal, flies nuisance in densely populated areas, and availability of sufficient water of feed quality may increasingly lead to legislative restrictions and costs involved in preserving protection.

Development of Acquired Immunity

Anticoccidials (Table 1) used in poultry may affect stages of the parasite inducing immunity.

Pullets intended as commercial layers must develop immunity to coccidiosis when they receive preventive drugs. However, **anticoccidials**, which are effective against second-generation schizonts, can seriously delay the development of immunity if they are given at the dose levels recommended for broilers. Therefore, they should be fed at the lowest possible dose level and for the shortest practical period that give sufficient anticoccidial protection and allow progressive development of immunity in replacement pullets. One of the effects of immunity is to reduce the biotic potential of the coccidia; each ► **oocyst** of the common chicken coccidium *E. tenella* is theoretically able to produce about 2.5 million second-generation merozoites although this maximum number may only occur in the case of initial infection. In partially immune animals, however, only some of the parasites complete their life cycle and produce variable oocyst numbers. In completely immune animals a few or no oocysts are produced for prolonged periods of time; some of the parasites may persist in an asexual stage within the host and thus fail to get further than the initial stage of trophozoite or first-generation meront. As a result, immunity to a challenge inoculum usually leads to a reduction in the clinical signs and in parasite multiplication. The specificity of immunity to ► *Eimeria* spp. is well known, although there may be considerable strain variations in immunity in some species of coccidia in commercial poultry houses as has been shown with *E. acervulina* and the very immunogenic *E. maxima*. The duration of protective immunity is uncertain and depends on several factors like mode of immunization, inoculum dose, age of the host, as well as on *Eimeria* spp. and strain variation. It is not yet clear whether immunity is of the sterile or premunition type. It seems likely that immunological control of poultry coccidiosis is achievable. In the not too distant future it will replace ► **chemoprophylaxis** coming increasingly under public pressure because of drug residues in edible tissues and occasionally in eggs (► **Chemotherapy/Withdrawal Time of Drugs in Target Animals**). ► **Vaccination** with attenuated or precocious strains of *Eimeria* spp. will be therefore an attractive alternative for parasite control since it

lacks residual problems. In general, anticoccidials do not adversely affect build up of immunity after vaccination programs against bacterial and viral infections.

Coccidiosis in the Domestic Fowl

The disease is responsible for considerable losses in the poultry industry. Rearing of thousands of birds on litter-covered floors in enormous houses may result in a tremendous and dangerous buildup of the oocyst population (► *Eimeria*). A change from litter-covered floors to wire-floored pens greatly reduces the exposure to coccidia. Thus, outbreaks of coccidiosis in laying hens maintained in cages rarely occur. In general, the prophylactic use of anticoccidial drugs is not required if the cages are kept clean and the feces do not contaminate watering and feeding systems. However, discouraging results have been obtained from experiments to convert broiler and breeder flocks entirely to cage operations (the most obvious problems being high equipment and maintenance costs, breast blisters, leg problems, removal of droppings and dead birds, and housefly control). Today most poultrymen rely on **floor rearing methods** for broiler production or breeder flocks and use continuous medication programs. Poultry producers also attempt to control coccidiosis by employing good sanitary programs. Litters should be kept dry so that oocysts cannot sporulate – many outbreaks occur after leaks in roofs or waterers. Wet litter must be cleaned out and replaced with dry litter. When broiler houses are emptied for a new batch of chickens the litter should be piled up for about 24 h so that the heat generated can destroy the majority of oocysts. **Disinfection** is usually impractical since oocysts are resistant to disinfectants used against bacteria, viruses, or fungi. In parasitology laboratories where disinfection is needed, heat (30 min at 60 °C) or “effective” fumigants such as ammonia and methyl bromide may be used.

Despite the use of continuous medication programs (see “Drugs Acting on Coccidiosis of Domestic Fowl,” Table 1), coccidiosis is still the

most important parasitic disease in chickens. As a rule young birds are prone to mixed infections and older birds are carriers. In many outbreaks, however, clinical signs can be ascribed to one species or a combination of two or rarely three; signs of coccidiosis become apparent about 3 days after infection; chickens cease feeding and huddle together for warmth; on the fourth day of infection blood may appear in the feces.

The *Eimeria* spp. of the domestic fowl show marked differences in their **pathogenicity**. *E. tenella* is the most pathogenic and important species occurring in the epithelial cells and submucosa of the ceca; it may produce severe hemorrhagic enteritis, which leads to high mortality in young birds. *E. necatrix* is also a common and highly pathogenic species, which occurs in the small intestine (first- and second-generation schizonts) and in the ceca (third-generation ► **schizont** and gamonts). It tends to cause predominantly chronic enteritis in older birds but in acute cases severe submucosal hemorrhaging and even death may occur. *E. acervulina* (probably the most common species seen) occurs in the small intestine. The pathogenicity of *E. acervulina* strains may vary, and the clinical signs consist of weight loss and watery, whitish diarrhea. *E. maxima* is also common; it occurs in the small intestine and is moderately pathogenic causing numerous petechial hemorrhages and a marked production of mucus. *E. brunetti* is markedly pathogenic but relatively uncommon. In heavy infections, characteristic necrotic (hemorrhagic) enteritis is evident in the lower small intestine, colon, and tubular part of the ceca. *E. mitis* is common worldwide and occurs throughout the small intestine, even in the tubular part of the ceca. This species is slightly or moderately pathogenic; in severe infections numerous petechial hemorrhages may be present. *E. mivati* is fairly common in the USA and Canada (presumably worldwide) and seems to be more pathogenic than *E. acervulina*. It primarily occurs in the upper small intestine and has been included by several authors as a variant of *E. acervulina*. The pathogenicity of *Eimeria* spp. in particular that of *E. acervulina* and *E. tenella* seems to be reduced by intestinal digesta viscosity reducing enzymes

as xylanases, glucanases, and pectinases. These enzymes may improve the nutritional value of wheat- or maize-based diets but mechanisms involved in reducing growth depression in coccidial infections are not yet known and need to be elucidated.

Economic losses due to **subclinical infection** of avian coccidia are enormous and much more common than coccidiosis, and coccidiasis should be regarded as ubiquitous in commercially reared poultry. Because some species of coccidia are highly pathogenic while others are only slightly or moderately pathogenic the species present must be identified. Scrapings from the mucosal surface of the intestine of affected birds should be examined microscopically for oocysts and endogenous stages of the parasite, and the location and type of lesions determined to establish a definite diagnosis.

Coccidiosis of Turkeys

The disease may cause heavy economic loss in the turkey industry; it is primarily a disease of young turkey poults (aged 3–10 weeks); older birds are carriers. **Clinical signs** are enteritis, watery or mucoid diarrhea, and ► **anorexia**. The most pathogenic and important coccidia are *E. meleagrimitis* (located in the jejunum) and *E. adenoides* (located in the lower ileum, ceca, and rectum); several species (in particular *E. innocua*, *E. subrotunda*, and *E. meleagridis*) are nearly nonpathogenic. Therefore, oocysts of the latter species must be differentiated from the pathogenic ones as well as those of *E. gallopavonis* (lower small intestine, ceca, and rectum) and *E. dispersa* (duodenum, jejunum, ileum), which are not so common, and only slightly or moderately pathogenic. The presence of oocysts (even large numbers) in the feces can only be a tentative diagnosis for coccidiosis; satisfactory diagnosis can only be made at postmortem.

Coccidiosis of Geese and Ducks

The disease seems to be of relatively little importance although several homoxenous coccidia are known. Some of these may be associated with severe disease and even death. *E. truncata* is

highly pathogenic to goslings, and occasionally causes up to 100 % mortality within a few days; older birds are carriers. This species occurs in the kidney tubules; its endogenous stages destroy the epithelial cells, causing enlarged and light-colored kidneys. Other species (goose: *E. anseris*, *E. nocens*, *E. truncata*, *E. kottani*, duck: *E. kottani*, *E. danailovi*, *Tyzzeria pernicioso*) appear to be important in areas where crowding and poor sanitation are present. Thus, large numbers of sporulated oocysts in a muddy environment often lead to sporadic outbreaks of intestinal coccidiosis.

Action of Drugs on Developmental Stages of *Eimeria* spp.

The terms coccidiostatics and coccidiocidal (coccidiocides) for drugs, which characterize actions on coccidia, are often used confusingly. Drugs with a **coccidiostatic action**, such as clopidol or decoquinate, dinitolmide (Table 1), arrest the development of certain parasite stages in a reversible way; thus withdrawal of the drugs leads to completion of the life cycle and possibly the appearance of clinical signs several days after medication is discontinued. Drugs with **coccidiocidal action**, such as arprinocid, halofuginone, polyether antibiotics, toltrazuril, diclazuril and clazuril (Table 1), kill or irreversibly damage most of certain parasite stages, and there is no evidence of clinical relapse after drug withdrawal. Some drugs (e.g., nicarbazin, amprolium) may have both coccidiostatic and coccidiocidal activity depending on how long the drugs and in which concentration they have been given in the feed or water. Continuous medication of these drugs for more than 48 h usually results in the majority of parasitic stages being damaged. Polyether antibiotics mainly affect asexual *Eimeria* stages as sporozoites, schizonts of the first and second generation. Flow cytometric analysis has been shown to be a reliable and sensitive technique for characterizing coccidiocidal effects on sporozoites exposed to various ionophores in vitro. Diclazuril acts against most stages of *Eimeria* spp. but this may vary between species (e.g., in *E. maxima* gamonts

only); this is also true for clazuril. Prophylactic drugs may preferably act on early and/or late asexual stages in the life cycle, like polyether antibiotics, decoquinate, clopidol, robenidin, nicarbazin, halofuginone, diclazuril, or amprolium + ethopabate. A few **therapeutic drugs** used for treating outbreaks of coccidiosis may affect stages of second- and third-generation schizogony and to a certain degree ► **gamonts** (sexual stages) as well; drugs reducing clinical signs of coccidiosis are amprolium, sulfonamides, clazuril, toltrazuril, and combinations of sulfonamides + dehydrofolate reductase inhibitors (Table 1). Toltrazuril administered in drinking water has brought substantial progress in treatment of coccidiosis in various animals. It has a broad spectrum of activity against various parasitic protozoa, and unlike other anticoccidials, it acts against schizonts and gamonts of various ► *Eimeria* and ► *Isospora* spp.

Drugs Acting on Coccidiosis of Domestic Fowl

Today, chemoprophylaxis in continuous medication programs appears to be the only effective tool for controlling coccidiosis in floor-reared poultry although drug resistance in *Eimeria* spp. populations is a widespread problem in the broiler industry today. Strategic use of anticoccidials may thwart the development of resistance processes. However, neither improved sanitation nor vaccination of birds with pathogen species of live precocious oocysts (e.g., Paracox, Livacox, see “► **Coccidiosis, Animals**,” Table 1) via drinking water or feed can sufficiently substitute continuous medication programs today. The prophylactic use of anticoccidials is based on the application of additives in-feed, i.e., drugs are added directly to bird feed in small quantities, usually in concentrations of a few ppm (part per million). Such anticoccidials are approved by governmental agencies for use in growing birds (e.g., chickens, turkey, others). Thus, prescribed concentration rations of these drugs can be fed to licensed table birds ad libitum from the beginning of their life (fattening/growing period) to a

prescribed preslaughter withdrawal time, or age at first egg, or start of cage or battery keeping of pullets. Additives in-feed used worldwide for the prevention of poultry coccidiosis and therapeutic anticoccidials are listed in Table 1. There are (1) synthetic compounds (e.g., amprolium, clopidol, decoquinate, diclazuril, halofuginone, nicarbazin, or robenidine), (2) polyether antibiotics or ionophores (lasalocid, maduramicin, monensin, narasin, salinomycin, semduramicin), and (3) drug combinations (e.g., amprolium + ethopabate, narasin + nicarbazin, maduramicin + nicarbazin). Most **continuous medication** programs may last 35–40 days, i.e., from the beginning of the fattening period to a fixed time prior to slaughter of birds. **Withdrawal times** (“► [Chemotherapy/Withdrawal Time of Drugs in Target Animals](#)”) for most prophylactically used anticoccidials may last 0–5 days and longer (e.g., toltrazuril, 14 days), or may exceed 5 days for other reasons, e.g., to minimize costs, or to promote “compensatory growth.” A withdrawal time longer than 5 days may lead to enhanced risk of coccidiosis at the end of fattening period, particularly if environmental ► [hygiene](#) is poor. The prophylactic use of anticoccidials in-feed in **egg-laying birds** is not permitted, although the occurrence of residues of anticoccidials in eggs has been widely proven; carryover of medicated feed in the feedmill or elsewhere must be the cause. Sensitive and specific analytical assays, as spectrophotofluorometry, liquid chromatography, high performance liquid chromatography (HPLC), the qualitative vanillin test and others, are available to detect the parent compound (metabolites) or their residues in feed, edible tissues, and eggs of target animals or nontarget animals. In case of outbreaks of coccidiosis **therapeutic drugs** (e.g., amprolium, sulfonamides, dehydrofolate reductase inhibitors plus sulfonamides, toltrazuril) are preferably administered via drinking water for a 3- or 5-day treatment course, and withdrawal periods may exceed 14 days. In practice, this means that medication towards the end of the growing life of birds is not economically possible, and this is also true for drugs used outside their product license; such drugs may also require withdrawal periods that exceed 14 days. So often the medicines regulations

how they relate to the withdrawal periods stipulated for therapeutic drugs and given to food animals withhold birds (meat chickens, ducks, turkeys) from the possibility of treatment for a significant part of their life.

Drugs Acting on Coccidiosis of Turkeys, Geese, Ducks, and Gamebirds

Approved additives in feed, and maxima concentrations (EC directives, for new regulation 1831/2003: use of additives in animal nutrition cf. last page of Table 1) for prevention of coccidiosis in turkeys are shown in Table 1. Drugs may be e.g., amprolium + ethopabate, diclazuril, halofuginone, lasalocid, monensin, and robenidine. The turkey industry (mainly found in the USA) has till now been rather small compared to that of chicken broilers. The most suitable drug program in turkeys is continuous medication but anticoccidial treatment covers only a part of the growing period of birds (till 12–16 weeks of age or 8–10 weeks of age if birds are moved to outside pastures or larger facilities). At this time ► [acquired immunity](#) may be established in most of the birds; however, some birds may still be susceptible to damaging infections 12 weeks after the growout start. Intermittent medication is used relatively often since continuous anticoccidial programs are not universally practiced with turkeys up to 8 weeks of age because of the high resulting costs. Concentrations in the feed are generally in the same range as those administered in chicken broiler rations. There is evidence from field experience that drug resistance in coccidia of turkeys may exist. Generally it seems not to be a major problem although monensin resistance has been demonstrated in *E. meleagritidis* field isolates. Under experimental conditions a drug sensitive laboratory strain became resistant to the drug after ten generations of selection.

Drugs Acting on Coccidiosis (Eimeriosis) of Ruminants and Horses

Bovine ► [eimeriosis](#) (the most pathogenic species are *E. zuernii* and *E. bovis*) is primarily a

disease in calves between the ages of 3 weeks and 6 months; older calves and adult animals are usually symptomless carriers. Crowding and lack of sanitation greatly increase outbreaks of disease. Coccidiosis in sheep and goats is often a disease of feedlot lambs, and often occurs in breeding flocks. Mixed infections build up to a peak that may last 1–4 weeks and then decline. *E. ovina* (sheep), *E. ashata* (sheep), *E. ovinoidalis* (sheep), *E. arloingi* (goat), and *E. christenseni* (goat) are of clinical importance. Batch rearing of lambs or calves in groups of similar ages may limit the buildup and spread of oocysts to younger animals thereby targeting potential treatment measures. Little information is available on the eimeriosis of **equines**, mainly caused by *E. leuckarti* in the small intestine or *Klossiella equi* in the kidneys of foals. Coccidiosis in horses (including asses and mules) seems to be very rare. Beware of polyether antibiotics in-feed in environment of horse facilities; they are highly toxic to equines.

Most drugs used in **cattle** are approved for the prevention of coccidiosis in poultry. The demand for grainfed beef has led to cattle rearing techniques (large feedlot complexes) that may encourage damaging infection pressure. Only a few drugs have been approved for treatment in cattle by some governments. **Decoquinat** (Table 1) is approved in several countries for the treatment and prophylaxis of bovine coccidiosis. The tissues of treated calves that had been on continuous medication with decoquinat were free of schizonts, gamonts and oocysts. The drug apparently kills *E. bovis* sporozoites or arrests their further development if administered at 1.5 mg/kg b. w. in-feed.

Coccidiosis in bovines is often wrongly considered to be a sporadic disease with the result that drugs have rarely been used for prophylaxis. Outbreaks of the disease are still handled by spot treatment using therapeutic drugs as sulfonamides, e.g., sulfaguandine, sulfamethazine, and sulfadimidine or sulfaquinoxaline. Combinations of sulfonamides with trimethoprim are used in manifest coccidiosis in cattle, sheep, and goats. Decoquinat or amprolium (Table 1) are also effective against bovine coccidia. Amprolium

and lasalocid are used in the USA for treatment of clinically ill calves and lambs. **Toltrazuril** (15 mg/kg $\times$ 1 orally) is very effective against bovine coccidiosis of cattle, sheep and goats (Table 1). **Preventive drugs** such as ionophorous antibiotics (monensin, or salinomycin) only approved for prevention of coccidiosis in poultry also exhibit distinct activity against coccidiosis in ruminants. The doses of monensin, and salinomycin used for improving feed efficiency in feedlot and pasture cattle correspond to the doses reported to prevent coccidiosis; it is assumed that the anticoccidial “side effect” of these “growth promotors” may considerably reduce coccidiosis problems in feedlot cattle. Calves artificially infected with *E. bovis* (88 %) and *E. zuernii* were given lasalocid in-feed at 0.50, 0.75, or 1.0 mg/kg b.w., daily for 45 days. There were no dose-dependent effects but equal reduction rates in oocyst output and preventing clinical coccidiosis. Calves given lasalocid, decoquinat, or monensin in-feed at 33 ppm for 46 days had significantly fewer oocysts in feces and fewer clinical signs of coccidiosis than those given nonmedicated rations. Mixing lasalocid in milk replacer or fresh milk (1 mg/kg b.w./day) is an effective method of protecting young calves against early infection with coccidia. **Decoquinat** can be also used as a feed additive approved for the prevention of coccidiosis in sheep and **goats** (Table 1). Ionophores in-feed such as monensin, lasalocid, or salinomycin prove effective also in preventing coccidiosis in sheep, and goats; against caprine coccidia they are, however, only moderately active. Treatment of coccidiosis in lambs and kids is done with drugs used in cattle. Often animals are clinically ill when the disease is diagnosed. At this time the intestinal mucosa is already extensively damaged, and consequently treatment cannot lead to a radical cure. As a rule, all lambs and kids in a flock should be treated, as even those showing no symptoms are likely to be infected. Fluid therapy using either oral rehydration solutions or parenteral solutions, and appropriate anthelmintic treatment are indicated in severely affected animals.

Drugs Acting on Coccidiosis (Eimeriosis) of Rabbits

Coccidiosis in rabbits is essentially restricted to the young (adults are carriers) and occurs particularly in breeding and rearing establishments (rabbitries) although outbreaks of coccidiosis in warrens or similar types of habitat are not uncommon. The most important species seems to be *E. stiedai*, which is common, worldwide and occurs in the walls of the bile ducts in the liver causing hepatic coccidiosis. Other important and pathogenic species, which may occur in the intestine, are *E. irresidua*, *E. magna*, *E. intestinalis*, *E. media*, and *E. perforans*; mixed infections are the rule. The presence of parasites in a case of enteritis does not necessarily indicate the cause. *Coccidia* may be present in large numbers without any serious clinical signs. Therefore, the most satisfactory diagnosis is made at postmortem; only the presence of characteristic lesions are evident in the liver/or the intestine.

There are only a few additives in-feed approved for the prevention of rabbit coccidiosis in Europe or elsewhere. These are robenidine (50–66 ppm), and salinomycin (20–25 ppm). Preventive administration of salinomycin in pelleted feed at 25 ppm may not only reduce markedly the oocyst production but lead to almost total inhibition of hepatic and intestinal lesions as well. Several **sulfonamides** can be used for the **therapy** of coccidiosis. They may be given in various routes and dosage forms (in-feed, in-water, and as injection). Their preslaughter withdrawal times may range between 8 and 15 days. **Sulfaquinoxaline** (relatively cheap and water soluble) seems to be the most widely used sulfonamide for treating rabbit coccidiosis, and it has been found to be just as helpful in preventing coccidiosis when given in continuous medication programs in feed or water. The drug of choice for treatment of intestinal and hepatic coccidiosis appears to be toltrazuril. However, a proper management and good hygiene in rabbitries can markedly reduce long-term medication and treatment with anticoccidials.

Drug Acting on Coccidiosis of Swine, Dogs, and Cats

Coccidiosis in **swine** is mainly restricted to young pigs; older pigs are carriers. *E. deblickei* and *E. scabra* are probably the most pathogenic species. *Isospora suis* has also been found to cause severe enteritis; however, intestinal disorders are so common in baby and young pigs and are caused by so many different pathogens that a diagnosis based only on fecal examination is not definite. Only a very large number of oocysts can indicate that coccidiosis is present. *Isospora suis* is an important causative agent of porcine neonatal diarrhea worldwide; it may occur on any farm with any type of management system and at any time of the year although feces samples of sows always proved negative. Most canine and feline coccidia are usually nonpathogenic or only moderately pathogenic; however, coccidiosis in **dogs** and **cats** may be an important cause of the diarrheic syndrome often associated with secondary infections in puppies and kittens. Affected animals are frequently seen in breeding kennels and runways where sanitation is poor. Diagnosis is not definite if it is only based on clinical signs (e.g., diarrhea with blood in the feces), or on the presence of large numbers of *Isospora* spp. oocysts in the feces; postmortem examination is the most adequate diagnosis method. Coccidial infections in dogs and cats may also be caused by heterogeneous genera (*Sarcocystis* spp. in dogs, and *Sarcocystis* spp. and *Toxoplasma gondii* in cats, see respective entries).

The most commonly used compounds for treatment of coccidiosis in dogs, cats (and piglets: Table 1) are **sulfonamides**, and **toltrazuril** affecting mainly later asexual stages of the schizogony cycle and to a certain degree sexual stages (gamonts). There are only a few controlled studies with experimental infections and no reliable evidence of practical problems associated with *Eimeria* spp. in swine. In contrast, *I. suis* infections appear to have become an economically important diarrheal disease in young piglets during the last two decades, and modern production systems seem to encourage the disease. Mortality due to *I. suis* infections may reach 10–20 % in

nursing pigs, and a similar percentage may be severely stunted. *I. suis* infections causing severe enteritis or even death in piglets have been treated successfully with amprolium (not approved indication); medication of sows with amprolium for 1–2 weeks before and after farrowing and of neonatal piglets may be helpful in reducing morbidity and mortality. Administration of toltrazuril in piglets (a single dose: 20 mg/kg, orally between 3 and 6 days of age) has been shown to reduce the morbidity in piggeries. There was a significant reduction in the number of antibacterial treatments given to piglets, fewer piglets developing diarrhea, and a significant improvement in growth rate of piglets. *I. suis* was detected in 38–50 % of fecal samples from several piggeries and in 93 % of those from the experimental piggery. Supportive treatment with antibiotics (e.g., chlortetracycline or oxytetracyclines) may reduce secondary bacterial infections in the intestine of piglets with severe enteritis. **Good sanitation** can effectively reduce diarrhea caused by *I. suis* infection in neonatal piglets in large farrowing facilities.

Drug Tolerance Problems in the Broiler Industry

A new successful drug should have competitive advantages over other available drugs, e.g., high potency and broad-spectrum activity. Furthermore, at the recommended doses the coccidia must not be allowed to develop resistance or to survive for a longer period. The reduction in coccidial sensitivity to any drug (partial drug resistance) encourages the development of subclinical or subacute coccidiosis. Low levels of infection usually cause a moderate drop in feed conversion and thus lead to considerable economic losses in the poultry industry.

The development of drug resistance may be evident if a change in the parasite can be demonstrated by comparing sensitivity before and after exposure to the anticoccidial. Possible causes for **drug failure** in the field may result from selection of resistant organisms, which rapidly become the dominant phenotype in broiler houses. Resistance is commonly believed to arise initially in the

presence of “subtherapeutic” or lower than recommended drug concentrations. Contrary to that suggestion, it has been argued that resistance may occur more rapidly in the presence of higher drug concentrations as a result of a more rapid change in gene frequency caused by increasing the intensity of selection. Studies on the incidence of drug resistance in the field and in experimental investigations have shown that resistance among strains of coccidia to **synthetic drugs** such as 4-hydroxyquinolines (e.g., decoquinate, methylbenzoquate), arprinocid, meticlorpindol, and halofuginone is relatively high. The resistance may result from the selection of preexisting mutants in the parent population. Thus drug resistance appears to be a genetic trait and tends to remain in a coccidia population for some years. Recent investigations on intraspecific polymorphisms of *Eimeria* spp. due to drug resistance indicate that differences in drug sensitivity correlate with genetic differences and polymorphisms detected by random amplified polymorphic DNA (RAPD) might facilitate the selection of molecular markers for resistance genotyping.

In vitro studies on uptake of [^{14}C] monensin by *E. tenella* sporozoites in primary chicken kidney cell cultures infected with ionophore-sensitive (IS) or ionophore-resistant (IR) isolates showed significant differences in [^{14}C] monensin accumulation between IS and IR isolates. The latter isolates had decreased uptake of monensin and the amount of the drug required to inhibit development of *E. tenella* by 50 % was 20–40 times higher for IR isolates of *E. tenella*, which might reflect differences in membrane chemistry. Studies on an *E. tenella* field isolate that was resistant to monensin, salinomycin, and lasalocid at double-use level and resistant to narasin and maduramicin at normal-use level showed good agreement between in vitro and in vivo results. Flowcytometric analysis of fluorescence after simultaneous exposure to fluorescein diacetate (FDA) and propidium iodide is a suitable indicator of cellular viability and proved to be a valuable technique in the study of ► **sporozoite** response to anticoccidials. Thus, various improved in vitro techniques in research programs have become increasingly important in recent years. They may

be a supplement to and, occasionally, a substitute for in vivo experiments in certain fields of the basic research, as in the field of biotechnology of poultry and farm animals. A first practical approach to countering **drug resistance** in the field may be an increase in the drug concentration. Increasing the drug concentration to compensate drug tolerance of coccidia is not only uneconomical but can also lead to toxic problems since several anticoccidials (e.g., nicarbazine, halofuginone, and various ionophorous antibiotics) are used at doses which are close to toxicity levels in birds. With the exception of some ionophorous antibiotics, such as monensin, salinomycin, and lasalocid, none of the synthetic drugs introduced have enjoyed prolonged marketability without developing tolerance problems in the broiler industry. The continuing success of the ionophorous antibiotics (monensin was introduced in the USA in 1971) is a result of their broad-spectrum activity, and possibly because resistance in coccidia may not be able to develop by the mechanisms known to occur for synthetic drugs. There have also been early reports that monensin “resistant” *E. maxima* strains may be present in the field. Later selected *Eimeria* spp. from broiler farms in the USA and Europe revealed that control of some isolates to *ionophorous drugs* was poor although none of the isolates judged in sensitivity tests was found to be completely resistant to the ionophores tested. Thus, prolonged use of ionophores in poultry units for nearly 10 years led to a decrease in their anticoccidial activity. Salinomycin provided the best overall control, followed by lasalocid and monensin. The latter findings are in agreement with results obtained from field studies on the comparative efficacy of salinomycin and monensin in 17 controlled field trials. They included more than two million broilers and were carried out in several European countries, and salinomycin at 60 ppm showed performance advantages over monensin at 100 ppm. Maduramicin proved to be more effective against ionophore-tolerant field isolates of broilers than monensin and narasin, but showed similar activity to salinomycin in reducing lesions and mortality and in protecting performance. Although **side-**

resistance (colateral resistance) among related ionophores such as monensin, salinomycin, and narasin may occur “cross-resistance” between maduramicin and unrelated ionophores has also been reported; it is believed by some investigators that maduramicin is effective against strains resistant to the other ionophores. Results from drug-sensitivity tests with isolates of coccidia from broiler chickens in the USA, Brazil, Argentina, and Europe suggested in many cases incomplete side resistance of coccidia to polyether ionophorous drugs. Some field isolates revealed even complete multiple **cross-resistance** to synthetic and polyether antibiotics including maduramicin, and semduramicin (latest ionophore introduced into the market). An *E. acervulina* laboratory strain, which was resistant to monensin by passaging the strain 14 times in the presence of the drug (100 ppm), was shown to be sensitive to lasalocid but not to maduramicin, narasin, and salinomycin. Cross-resistance between the latter ionophores may suggest a similar mode of action in coccidia. Thus, monensin, maduramicin, narasin, and salinomycin, preferentially form complexes with monovalent (e.g., Rb^+ , Na^+ , K^+ , Cs^+) rather than divalent alkali metals (e.g., Ca^{++} in case of lasalocid), which may mediate electrically neutral exchange diffusion cation transport across membranes. Contrarily, a monensin-resistant *E. meleagritidis* strain exhibited cross-resistance to narasin and lasalocid and a field isolate of *E. tenella* showed cross-resistance between lasalocid and several ionophores preferentially forming complexes with monovalent cations. To slow down development of drug resistance in coccidia alternate use of anticoccidials is widely practiced in the poultry industry.

Measures Against Drug Tolerance in the Broiler Industry

As shown by epizootiological investigations, coccidial drug resistance poses a serious economic problem to intensive poultry farming both in the USA, in Europe, and elsewhere. Today, there is therefore an increasing use of **shuttle** or

dual programs (rapid rotations), i.e., the switching of anticoccidials during broiler growout. The drug(s) to be switched should belong to different chemical classes (e.g., ionophore/synthetic drug or vice versa during starter/final phase of production) and should be effective at different stages of the parasites' life cycles. Any resistant coccidia, which appear during the use of the first drug, should be affected by the second. In **straight** or **slow rotation** programs a single and often the same drug may be used for several broiler growouts (e.g., about 6 months; each fattening period may last 35–40 days or longer); it is then replaced by an alternative drug. Shuttle programs are still being discussed with regard to their value in delaying drug resistance. Although alternation of the drugs between crops may delay the appearance of resistance, it is likely that the outcome will be the acquisition of multiple resistance. There may also be the risk of underdosing or insufficient activity of drug mixtures resulting from switching the drugs. This might allow resistance to be developed faster. However, by switching the drug, underdosing can be excluded if new and exactly medicated feed is poured onto remaining feed; then the two drug fractions at the base of the silo funnel must add up to 100 % of any resulting mixture. Mixtures of ionophorous antibiotics were as effective in controlling drug-sensitive *E. tenella* and *E. acervulina* infections as a single antibiotic mixed in the feed at recommended prophylactic concentrations. However, such mixtures (e.g., monensin + narasin or salinomycin) may have limited additive action if there is already a partial resistance to one of the partners. In these experiments it was also shown that combinations of ionophorous antibiotics and synthetic drugs are complementary, even against field isolates with unknown drug response.

Drug combinations (Table 1) have commonly been used for synergism in order to minimize the occurrence of drug resistance (e.g., Lerbek roxarsone + clodolol), or to extend the species spectrum to all six pathogenic *Eimeria* spp. in chickens. Amprolium, which shows activity against *E. tenella* and *E. necatrix* have been combined with ethopabate and organic arsenicals respectively, in order to expand their spectrum to

include the upper intestinal species *E. maxima*, *E. acervulina*, and *E. mitis*. The only experimental evidence of retardation of drug resistance by synergistic effects of drugs was seen with methylbenzoate + clodolol (discontinued); complete resistance occurred to methylbenzoate 10 ppm and meticlorpindol 125 ppm, respectively, after three passages of *E. maxima*, but not with a 8.35 and 100 ppm combination of the two drugs.

To keep up their competitive position with other anticoccidials, narasin (and maduramicin) have been combined with nicarbazin, an old-timer among anticoccidials; these products, however, reveal no performance advantages over related monodrugs.

Drugs Acting on Cryptosporidiosis in Birds

Species of the genus ► *Cryptosporidium* are coccidian parasites that infect epithelial cells (extracytoplasmic) of the intestinal and respiratory tract of vertebrates (see Opportunistic Infections). Although immunocompetent hosts show no, or only mild, clinical signs after *Cryptosporidium* infections, particularly young birds under stress may suffer from life-threatening watery diarrhea, or severe respiratory symptoms. Cryptosporidiosis in chickens, turkeys, quail, and pheasants is usually manifest as respiratory disease caused predominantly by *C. baileyi* or as enteric disease (small intestine) caused by *C. baileyi* and *C. meleagridis*. The severity of infection depends on the immunocompetence of the host. Infections are due to aerosol transmission of infective oocysts coughed up by carrier (seeder) birds, or may be transmitted by feed or water supplies containing sporulated oocysts derived from feces of infected birds. Clinical signs in birds are coughing, mucoid discharge, dyspnoea, diarrhea, ► dehydration, weakness, and weight loss.

Causal therapy and chemoprophylaxis of chicken cryptosporidiosis with ionophorous antibiotics is problematic. Many approaches to anticryptosporidial efficacy of commercial drugs have failed to improve symptoms in birds

suffering from *Cryptosporidium* infections. Several other anticoccidials as sulfonamides, lasalocid sodium, halofuginone, and decoquinate, or other antibiotics (e.g., paromomycin) have proved to be insufficiently effective in controlling or even eradicating *Cryptosporidium* infection in birds. The drugs may exhibit positive short-term effects such as improvement of watery diarrhea and reduction of oocyst output in feces due to their “static” rather than “cidal” action on cryptosporidia.

Coccidia of Humans

Coccidia that may cause clinical signs in humans are rare. ► *Isospora belli*, a single host species in the small intestine, may be responsible for mild intestinal symptoms in some cases. Infections due to heterogeneous species like ► *Sarcocystis* spp. (Sarcocystosis) or ► *Toxoplasma gondii*, and related protozoans with a two-host life cycle are seen more often, especially in areas where raw meat is eaten and human beings have contact with cats or other felines. Moreover, *Isospora belli*, *Cryptosporidium parvum*, *Toxoplasma gondii*, and *Cyclospora* spp. belong to the opportunistic protozoa associated with immunosuppression caused by HIV ► (AIDS), or other pathogens and pathogenic processes “► Coccidiasis, Man”.

Coccidiosis, Animals

General Information

The ► coccidia are members of the suborder Eimeriina. They are typically highly host-, organ-, and tissue-specific. Under natural conditions, most mammals pass small numbers of coccidial oocysts in their faeces, without apparent clinical effect. Coccidiosis becomes important as

a disease when animals are reared under conditions that permit the build-up of high numbers of infective oocysts in the environment. This is because the degree of damage caused by coccidia depends upon the numbers of parasites able to replicate in any given site, which depends firstly upon the numbers of infective stages (oocysts) ingested. This is different from other ► protozoa which may reproduce indefinitely by ► binary fission, until halted by host immunity or death. ► *Eimeria* infections are self-limiting because the parasites only pass through a limited number of asexual multiplications. Coccidiosis involves (extensive) destruction of the intestinal epithelia. The effects of intestinal coccidiosis in mammals vary with the host-parasite system. They are mainly related to malabsorption induced by villous atrophy and reduction of brush border enzymes, or to ► anaemia, hypoproteinaemia, and ► dehydration due to exudative enteritis and colitis caused by epithelial erosion and ulceration. High mortality may occur in ruminants infected by the most pathogenic species (see also ► Alimentary System Diseases, Ruminants).

Pathology

Cattle

About 15 species of *Eimeria* parasitize cattle; of these *E. zuernii* and *E. bovis* are potentially highly pathogenic. Other species, such as *E. auburnensis* may at times contribute to the general clinical picture. In general, the infection occurs in calves or weaned feeder cattle under 1 year of age, but clinical disease occasionally occurs in adults, especially if massive infections are acquired during stressful situations. The diseases caused by *E. zuernii* and *E. bovis* are very similar; they are characterized by a haemorrhagic ► diarrhoea which may become so severe that pure blood is passed instead of faeces. Tenesmus is marked, and there is anaemia, weakness, ► anorexia, and emaciation. In severe infections death may occur. The first clinical signs appear just before the peak in oocysts output (day 18–19), when there is maximal loss of epithelium in the large intestine due to destruction of cells by second-generation

► **schizogony** and ► **gamogony**. This causes the exposure of the lamina propria and the formation of diphtheritic membranes. The destruction of the epithelium leads to reduction in the reabsorption of water, Na^+ and Cl^- from the intestinal contents. The abrupt loss of weight and the reduction of the plasma concentration of these two ions support this contention. Exposed capillaries of the large intestinal lamina propria may rupture, leading to loss of erythrocytes and plasma.

Sheep and Goats

Coccidial infection is virtually universal in sheep and goats, and large numbers of oocysts may be found in the faeces of clinically normal animals. Coccidiosis in small ruminants is chiefly restricted to young animals up to 4–10 weeks of age. Close morphological similarity between the oocysts of *Eimeria* spp. from sheep and goats has caused some confusion in the literature. Relatively little is known about the pathogenicity of the different species, but it has been established that *E. ovinoidalis* in sheep and its analogue in goats, *E. ninakohlyakimovae* can be very pathogenic. Other species such as *E. bakuensis* (*E. ovina*) and *E. crandallis* in sheep, and *E. arloingi* and *E. christensenii* in goats may exacerbate the symptoms of the former two species. Outbreaks of coccidiosis are usually acute and characterized by moderate ► **morbidity** and low mortality. There is a green or yellow watery diarrhoea with a fetid odour, occasionally with blood. ► **Abdominal pain**, some anaemia (macrocytic, hypochromic), loss of appetite, dehydration, tenesmus, weakness, and loss of weight occur. Depression, inactivity, and recumbency are prominent. Pathological changes include thickening of the caecum and colon mucosa, ► **oedema**, haemorrhage, and hyperaemia. Myiasis, bacterial diarrhoea, and bacterial septicaemia often accompany coccidiosis outbreaks.

Horses

The only species occurring in horses, *E. leuckarti*, is not known to cause disease.

Swine

At least 12 species of *Eimeria* are thought to occur in swine, and a single species of ► ***Isospora***. *Eimeria* spp. are not considered a major cause of disease in pigs and many animals are asymptomatic carriers. *I. suis* is the only important species. It causes porcine neonatal coccidiosis, a disease of piglets from about 5–6 days to about 2–3 weeks of age. It is characterized by a yellow, foul-smelling diarrhoea, dehydration, occasional ► **vomiting**, loss of condition, and death, or at the least a temporary check in growth. Morbidity is usually high, mortality low or moderate. Necropsy reveals villous atrophy and a marked, sometimes necrotizing, enteritis of the small intestine. Simultaneous infection of *I. suis* with viruses and *E. coli* results in more severe lesions and clinical disease than with coccidia alone.

Carnivores

There are at least 14 species of coccidia in canine faeces: *Isospora canis*, *Isospora* (*Cystoisospora*) *ohioensis*, *I. burrowsi*, *I. neorivolta*, ► ***Hammondia heydorni***, ► ***Neospora caninum***, and eight species of ► ***Sarcocystis***. A total of at least 15 species exist in cats: *Isospora felis*, *I. rivolta*, five species of ► ***Besnoitia***, *Hammondia hammondi*, ► ***Toxoplasma gondii***, and six species of *Sarcocystis*. In relation to pathogenicity, it is usually the intermediate hosts rather than the dog or cat that are adversely affected. Clinical coccidiosis in dogs or cats is apparently caused by certain species of *Isospora* and by *T. gondii*. For example *I. ohioensis* can cause clinical disease in newborn pups. Diarrhoea is caused by inflammation of the intestinal crypts, with necrosis and massive desquamation of the tips of villi, especially in the lower part of the small intestine.

Immunity and Vaccination

Reports from the literature suggest that immunity to coccidia is short-lived in young animals. In contrast, repeated coccidian infections induce a more long-lasting immunity than a single

Coccidiosis, Animals, Table 1 Live vaccines on the market

Trade name	Pathogenicity	Administration	Producer

Paracox-S	Attenuated	Water delivery (spray)	Schering-Plough
Livacox-Q, T	Attenuated	Water delivery	Merial Brasil, Biopharm Czech Republic

(primary) infection. An increasing infection pressure may cause a deterioration of immunity that is evident by an enhanced number of intracellular developmental stages and so, output of oocysts, and possibly the development of clinical signs. The effect of immunity can range from complete (or close on zero) inhibition of oocysts production (premunity) to the passage of smaller numbers of oocysts in the faeces (partial immunity). It is assumed that **premunity** (immunity of the non-sterile type) to coccidia depends upon the persistence of some (occult, extraintestinal) development stages in the immune host from initial infection and/or reinfection. Thus, the acquired (often) species- or even life cycle stage-**specific immunity** of the host to coccidia plays an important role in the control of parasites and may depend on various host factors such as individual immune status, age of the host and its genetic background (breed type: ► **innate immunity**). It seems that development of natural immunity to coccidiosis through digestion of sporulated oocysts is rather slow and may take several weeks or even longer. Therefore, using **vaccines** to prevent coccidiosis in the short lifespan of fattening young animals appears problematic because protective immunity resulting from vaccination may be insufficient. This is true particularly in case of broilers' life span which lasted about 35–40 days only. On the other hand, breeder replacement chicks and commercial layers are able to profit from the immunity protection

against coccidiosis. They may be exposed to a controlled number of sporulated coccidia oocysts, i.e., to **live virulent vaccines**. Today, various types of live vaccine for the control of poultry coccidiosis are available (see Table 1). Coccivac or Immucox (sporulated oocysts of wild-type) has been used mainly for replacement birds, which represent a relatively small market in comparison with that of the broiler industry. In using such vaccines it appears economically acceptable to have some loss of performance as a result of immunization. However, live virulent *Eimeria* vaccines for control of coccidiosis in broiler chicken have rarely been used because of loss of body weight, and its effect on feed conversion is not acceptable. **Attenuated parasites** for water delivery (spray) or gel delivery are “sub-lines” of sporulated oocysts from chicken derived from the progeny of single oocysts. They may be attenuated after long-term passages through the chorio-allantoic membranes of embryonating eggs (Livacox), or they may be recovered after only a few passages with selection for early development by passages through chickens (Paracox, Livacox) or rabbits. **Precocious lines** of coccidia species are drug sensitive and thus any use of anticoccidial drugs should be avoided during the month following vaccination. Precocious lines are characterized by a shorter life cycle, i.e., decrease in prepatent period, number, and size of endogenous stages (e.g., deletion of the terminal generation of schizonts of the wild-type parents). They

can induce protective immunity against coccidiosis in spite of distinct attenuation of their virulence. Such parasites (oocysts) are no longer able to cause infections with severe clinical signs in chickens or rabbits (the production of precocious lines in cattle obviously failed). Problems arising from vaccination in the poultry industry or elsewhere may be the delivery and application practice of such live vaccines. Thus the application management of vaccines seems to be more sophisticated than that of feed-in products in widely used ► [chemoprophylaxis](#). Another problem may arise through genetic instability in precocious sublines. In addition, cost of production of live “**cocktail**” **vaccines** containing all (Paracox) or only certain *Eimeria* spp. (Livacox) may be considerable and above that of in-feed delivered anticoccidial drugs.

The chances for developing protective recombinant vaccines against coccidiosis in **chickens** appear promising though *E. maxima* shows antigenic diversity, and live-*Eimeria* vaccines may show differences in their virulence and immunogenicity in the individual recipient and different breeds of poultry. The development of effective recombinant vaccines (genetically engineered *Eimeria* antigens) against poultry and farm livestock coccidiosis has become a major goal in modern parasitology. Since coccidiosis involves the intestinal immune system, understanding of the **complex gut-associated immune system** is most important in the development of immunological control strategies to coccidian parasites. **Different types of antigens** (surface-, internal-, secretory antigens of sporozoites, merozoites, gamonts) that induce parasite-specific immunity have been identified by means of monoclonal antibodies against various *Coccidia* species. Recombinant proteins derived from these antigens have been shown to induce either humoral or cellular response or both, whereas protection against live challenge (sporulated oocysts) proved to be insufficient to weak or partial only. For instance, responses of different poultry breeds vary considerably to such recombinant antigens

(epitopes). Sub-unit vaccines developed so far lack epitopes that induce strong protection and this seems to be also true for optimal delivery systems that release these epitopes at the site of infection. Suitable live recombinant vectors derived from bacteria or viruses will be necessary to induce a persistent stimulation of the local immune system by presentation of “perfect” recombinant target antigens to adequate immune effectors. Such approaches are only possible by using biotechnology that requires great skills of molecular biology as well as a profound knowledge of host immune responses to coccidian infection. Until now, there are large gaps in our existing knowledge concerning precise definition of target antigens and immune effectors. Consequently, the development of protective recombinant coccidiosis vaccines will be in any case a long-term and high-risk research project. Furthermore, such a vaccine must not only confer resistance but also be cheap and fit in with current management practice in the poultry industry and farm livestock. An exiting new approach to vaccine development may be highly attenuated bacterial vectors that have the ability to enter epithelial cells and direct plasmid DNA to the ► [cytoplasm](#) of the host cell for protein synthesis and processing for antigen presentation. **Delivery of DNA-encoded antigens** should permit mucosal immunization against the parasite simultaneously with multiple antigens that can stimulate T helper cells and antibody production, especially the proper folding and conformational epitopes for the immunoglobulins A (IgA) and G (IgG). Aside from the practical oral application of bacterial DNA delivery, this type of vaccines does not need DNA purification and can be produced for the fermentation, lyophilization, and packaging.

Therapy

Cochliomyia hominivorax

In this genus there exist four species, two of them are active in humans myiasis/*C. hominivorax* (Figs. 1 and 2) – (the New World screwworm fly), and *C. macellaria* (secondary screwworm fly).

C. hominis attacks besides man cattle, horses, sheep, goats, pigs, dogs, and many species of wild

life. The adults (Fig. 1) are common in slaughter houses (Southern USA, South America). The females lay up to 1,000 eggs in batches of 40–250. The larvae hatch in about 4 h and develop to adults in 6–20 days.

***Cochliomyia hominivorax*, Fig. 1** Larva

***Cochliomyia hominivorax*, Fig. 2** Adult

Cochlosoma anatis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Flagellated trophozoites of the ► [Trichomonadida](#) with a ventral attachment disc and six flagella. It measures 6–12 × 4–7 mm, is found in the cloaca, cecum, and colon of ducks and turkeys and was shown to be experimentally transmittable to chickens. This organism is apparently able to introduce enteritis.

Cocoon

There are several meanings:

- Cover of ► [puparium](#), inside which the adults of holometabolous insects (e.g., ► [fleas](#)) are developed.

- Chitinous ootheca of cockroaches containing 16–40 eggs (depending on the species).
- Egg-sack in annelids formed by ► [clitellum](#) to surround the fertilized eggs (e.g., *Hirudo*).
- Eggs of ► [trematodes](#) and other ► [Platyhelminthes](#), if they are composed of a ► [zygote](#) plus a number of vitelline gland cells.

Codworm Disease

Disease due to infection with anisakid worms (► [Anisakiasis](#)), e.g., from cods.

Coelom

Secondary body cavity (e.g., in annelids, vertebrates).

Coelotropha

Classification

Genus of ► [Protococcidia](#) ([Apicomplexa](#)).

Life Cycle

C. durchoni lives in the body cavity of the polychaete *Nereis diversicolor*, it has not schizogonic reproduction, see ► [Grellia](#) (syn. *Eucoccidium*) [dinophili](#). See also ► [Chromosomes](#).

Coenurosis, Animals

Coenurosis is a nervous system disease caused by the presence in the cranial cavity of *Coenurus cerebralis*, the larva of *Taenia multiceps* (► [Nervous System Diseases, Carnivores](#)). The infection occurs in sheep and less commonly in

other ruminants. It is rare in horses and man. In lambs, an acute meningoencephalitis may develop if a large number of immature stages migrate in the brain. More commonly, the infection follows a chronic course and is associated with the presence of 1 or 2 coenuri in the brain, 4–6 months after infection. The ► [coenurus](#) acts as a space-occupying lesion anywhere in the central nervous system. It occurs most often in the cranial cavity, sometimes between the hemispheres and cerebellum, and sometimes underneath, in the region of the mid-brain. Pressure signs develop slowly and are usually preceded by dullness, cessation of feeding, loss of weight, and the habitual resting of the head against any support. The ultimate signs depend upon the site of the cyst, and include blindness and incoordination, as well as the turning movement which is said to be characteristic of the infection. Other locomotor signs include reacting, stumbling, abnormally high or low carriage of the head, and lunging forwards. These signs occur in attacks of some minutes duration followed by a remission of one or more hours, but the background of dullness and abnormal head carriage is continuous. Eventually the animal becomes recumbent, and death soon follows. A case of coenurosis has been described in a bullock, which resulted in the development of hydroencephalus.

Therapy

► [Cestodocidal Drugs](#).

Coenurosis, Man

Coenurosis, is an infection with larval forms of the genus ► [Multiceps](#) of canids, which gives rise to small cysts in the brain typically with prominent multiple scolices, but without daughter cysts. These are surrounded by a layer of fibrous tissue. Degenerating cysts give rise to intense inflammatory reaction with symptoms depending on location. Fibrosis and calcification follow.

Therapy

► Cestodocidal Drugs.

Coenurus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,

Coevolution

Coevolution is an evolutionary change in two or more species resulting from reciprocal selective pressures.

In parasite-host systems, the demonstrations of

- Genetic variability in parasites for transmission to hosts and survival in hosts on the one hand,
- Genetic variability in hosts for avoidance of parasites and resistance mechanisms on the other hand

constitute what Hochberg and Crompton call “a cornerstone prediction of active coevolution.”

When reciprocal selective pressures occur, parasites and hosts are engaged in arms races. Coevolution between parasites and hosts might thus be a universal phenomenon, although it has been rarely demonstrated.

Optimal pathogenicity is at the cross-roads of two arms races: In a first arms race (the encounter arms race), the parasite selects genes to improve the probability of contact with the host whilst the host selects genes to avoid meeting infective stages of the parasites. In a second arms race (the compatibility arms race), the host selects genes to kill the parasite whereas the parasite selects genes to survive. The first arms race implies reciprocal behaviours whereas the second implies defence and ► [evasion mechanisms](#). A selective process in 1 of the 2 arms races can be compensated by a counter-selective process in the other; for instance, selection of adaptive behaviour in the parasite’s genome can be counter-balanced by selection of immune defence in the host’s genome. “Attack and defense invariably favor diversification . . . The biochemical mechanisms that mediate attack and defense determine the limits of diversification” (Frank).

Coevolution must not be confounded with parallel evolution. When a phylogeny of hosts and their parasites is established (for instance by comparison of DNA sequences or any other method), it can happen that host and parasite phylogenies are “parallel” (topologically identical) because parasites have regularly cospeciated with their hosts; in other cases, there is no congruence between the phylogenetic trees of parasites and hosts because a number of lateral transfers of parasites occurred between different host lineages. It is sometimes tempting to assume that parallel evolution and coevolution are linked to each other, or even synonymous. This is not true because coevolution implies that each partner has actually exerted selective pressures on the other and reciprocally. Cospeciation can result from external factors (for instance geographical isolation) which caused parasite and host to speciate synchronously, and not as a result of reciprocal pressures.

Examples

Parallel evolution of host and parasite, e.g., humans and their highly specialized lice species (*Pediculus*, *Phthirus*), live together since long, and the lice use exclusively humans as hosts.

Colonization

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Latin: *colonia* = settlement.

This term describes the process when agents of disease start development on surfaces or in cavities of hosts or when they enter a new biotope.

Colony Collapse Disorder

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes the breakdown of honey bee stocks due to infestation with ► *Varroa destructor* mites. In such cases the following compounds are used in different countries worldwide: coumaphos, bifenthrin, amitraz, endosulfan, monoterpenoids, oxalic acids, formic acids, carbamates, and organophosphates.

Colorado Tick Fever

Synonyms

CTF

Colorado tick fever is caused by the CTF virus (ungrouped ► *arbovirus*) and is chiefly transmitted by the tick *D. andersoni*. After an ► *incubation period* of 3–6 days there may be ► *encephalitis* and bleeding in children. Fatalities are rare.

Commensalism

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

This term describes a type of symbiosis between organisms, where one obtains benefits, while the other is unaffected or has slight benefits, so that it has not developed measurements to get rid of the other organism. Several gut trichomonads and ciliates apparently show this way of co-existence. This second form is often also described as ► *mutualism*.

Communities

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

In ecology, the word community designates a set of populations of different species which occupy, at least partially, the same environment and are susceptible to interact. In parasitology, the meaning is the same, with the particularity that it is always difficult to decide what are the limits of a community.

In general, a parasite community is considered as consisting of parasites of different species susceptible to interact in the same organ of the same individual host. It is more correct to call this community an *infracommunity*, since it is composed of several *infrapopulations* (► *Populations*). For instance, the parasites which inhabit the digestive tract of a host constitute a *infracommunity*. It is clear that the definition of the *infracommunity* can be restricted (for instance to the duodenum) or enlarged (e.g., to

Communities,

Fig. 1 Populations and communities as defined by various authors (original). Gray boxes represent individual hosts of species *X*, *Y*, etc. Letters represent individual parasites of species *a*, *b*, *c*, *d*, *e*, etc.

the entire host, because, even in the absence of physical contacts, parasites in a same individual host can interact in a number of ways).

The difficulties increase if one considers the community at a scale greater than that of the individual host.

Holmes and Price, among others, accepted the following definitions:

In general ecology, a component community is an assemblage of species associated with a particular "microenvironment" (e.g., species living

in tree holes); in parasitology, all the infracommunities in a population of hosts make up a component community.

In general ecology, a compound community is a mixture of component communities that interact to various degrees (e.g., species living in a forest); in parasitology, all parasites in an ecosystem, whatever their stage of development, constitute a compound community.

Combes suggested to simplify and homogenize the terms: a community of parasites

comprises all the parasites of an ecosystem, a xenocommunity comprises all the parasites of a particular host species of that community, and an infracommunity comprises all the parasites of a particular individual host (Fig. 1).

Competition, Interspecific

The level at which different species of parasites can interact (and thus in which interspecific competition can occur) is that of the infracommunity (► [Communities](#)).

Infracommunities are thought to range from isolationist to interactive, but there have been two main tendencies concerning the degree of interaction.

Price and Rhode think that infracommunities are principally isolationist because the host is rarely saturated. When different parasite species occupy different “niches” in a host (e.g., distributed along the digestive tract of a bird or at particular places of the gills of a fish), this is not the result of a competitive displacement, but rather of habitat preferences. In the case of monogeneans, which are ectoparasites on the gills, Rohde suggested that the gathering of different parasite species in particular areas has been selected to facilitate genetic exchanges between individuals when densities are low and do not reflect interspecific competition.

Holmes is more in favour of interactive communities, especially in the intestines of birds. Bush and Holmes, for instance, have demonstrated that the intestinal ► [helminth](#) species of lesser scaup ducks are arranged in a strictly predictable pattern and that high densities of certain species provoke displacements of less competitive species. The occupation of different organs or parts of organs by the different species of an infracommunity is seen as the result of selective pressures. When a niche appears to be empty, this can be a “ghost of competition past.” Bush and Holmes have applied the notion of core and satellite species to parasite communities with success: core species constitute the predictable component

of the community, are often specific to the host and compete for space and resources; satellite species are unpredictable, generalist, and do not intervene in the structure of the community. Satellite parasites in a given host species can be core species in another host.

Competition, Intraspecific

Intraspecific competition is the rule on earth, and is one of the important mechanisms underlying regulation of populations. Individuals of a same species compete for space, for resources, for mates. Competition can be by exploitation (what is taken by certain individuals is no longer available for others) or by interference (individuals show direct or indirect aggressiveness to each other). The consequence of intraspecific competition is a reduction of ► [fecundity](#) and/or survival (which affects part or all of the populations), which contributes to regulate the populations. The effect is density-dependent: when density increases, competition increases, so that fecundity and/or survival decrease in proportion.

Intraspecific competition is one the major components of regulatory processes in parasite populations. Surveys as well as experiments have often demonstrated that the density of parasites in a host cannot exceed a certain level. It is, however, always difficult to separate the effects of competition from the effects of immune defence, which are also density-dependent. One of the most convincing demonstrations of intraspecific competition is the “enlargement of the niche”: in the gut of a vertebrate, for instance, it is possible to determine what location is preferred when the individuals of a parasite species are in low densities; this is the “preferendum” of the species. When the size of the ► [infrapopulation](#) increases, a part of the individuals are constrained to occupy less favorable places, sometimes far from the preferendum. It is then easy to show that these individuals have a ► [reduced fecundity](#) and/or size. However, not all infrapopulations show signs of intraspecific competition: hosts are

sometimes far from being saturated
(► [Competition, Interspecific](#)).

Complement Evasion *Borrelia burgdorferi*

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Borreliosis is one of the most common tick-borne diseases in man and animals. Recent studies have shown that there are three pathways to activate complement on the outer membrane of *B. burgdorferi* and thus to initiate defense mechanisms.

- **Classical pathway:** protein C1q binds to the pathogen surface activating complement C4 and C2.
- **Lectin pathway:** mannose-binding lectin or ficolin (in complex with serine protease and small mannose-binding lectin associated protein) bind to polysaccharids on the pathogen's surface.
- **Alternative pathway:** in this case the continuous spontaneous hydrolysis of C3 into C3-H₂O is involved. The latter binds and stabilizes the alternative C3 convertase C3bBb.

Complement System

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This system comprises in humans about 30 proteins, which are included in the blood plasma and which serve as unspecific defense system against penetrated agents of diseases. These proteins support the immune system in the recognition of the invaders and stimulate it to produce relevant antibodies (e.g., immunoglobulins). During an infection such complements were concentrated at reaction sites, where inflammation processes have started and would be fatal, if not regulated by a control system.

Compliance

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Latin term describing the acceptance of a medical treatment of a parasitosis respectively of another disease.

Compound Eye

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The eyes of insects and crustaceans are composed of several single ommatidia, which are everted eyes containing eight nerve cells, and a cuticular

lens plus lateral covering cells. Dragonflies have up to 40,000 single eyes in their compound eyes. See e.g. Figs. in chapter Black flies (*Simulium* sp.).

Concealed Antigens

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes antigens obtained from ticks, which are normally not in contact with the immune system of their hosts. They were used to produce in Australia a vaccine against ► *Boophilus* ticks (*B. microplus*) that are vectors of ► *Babesia* species of cattle.

Concentration Methods

Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes the fact that an existing active infection with an agent of disease prevents additional infections by members of the same group.

For example, persisting adult filarial worms lead to immune reactions that block (at least partially) growth of invading new larvae three of the same group.

Concomitant Infections

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes the fact when hosts are infected by two similar parasites, which may influence diagnosis results. For example, in some African countries microfilariae of different filariae may occur in the same host and can be diagnosed by wet blood film and concentration methods. Species diagnosis is absolutely needed in order to avoid treatment of nonpathogenic parasites.

Concrement Vacuole

Inclusion with sensory activity inside ciliates of the family Büttschliidae inside the alimentary channel of mammals (e.g., *Blepharoprosthium*).

Congo Floor Maggot Myiasis

Disease of humans in Africa due to the activity of nightly sucking larvae of the fly species *Auchmeromyia luteola* (syn. *Senegalensis*). The larvae are thought to be mechanical vectors of trypanosomes.

Conjugation

Sexual process during which two stages of ► [Ciliophora](#) (= conjugants) fuse for a short while with each other and exchange a so-called wandering ► [micronucleus](#), thus executing DNA exchange. After this process the cytoplasmic bridge is broken off, each individuum lives on its own, and finally starts reproduction by ► [binary fission](#). (See also ► [Balantidium coli](#), ► [Ichthyophthirius multifiliis](#)).

Connatal Infection

Name

Latin: *connatus* = during birth.

Infection of the newborn during birth (e.g., ► [malaria](#) and ► [AIDS](#) may then become transmitted).

Connatal Toxoplasmosis

Disease due to infection with ► [Toxoplasma gondii](#) being already present during birth

(prenatal infection; Latin: *natus* = birth) via the intrauterine way (= congenitally). This infection may only occur in pregnant women who were infected for the first time during pregnancy. ► [Prenatal Toxoplasmosis](#).

Connexivum

Lateral fortified portion of the abdomen of some bugs (e.g., Triatomae), not covered by the wings.

Conoid

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The conoid (Figs. 1 and 2) is a hollow truncated cone composed of spiraling microtubules

Conoid, Fig. 1 TEM of the anterior pole of a coccidian cyst-merozoite (= bradyzoite) showing the conoid being protruded anteriorly to the polar ring system, at which the subpellicular microtubules are attached. This picture is obtained by negative staining

Conoid, Fig. 2 Diagrammatic representation of the anterior pole of motile coccidia with a ► [conoid](#) (e.g., *Eimeria*) – this stage has two polar ring systems (PR₁/PR₂). C conoid consisting of microtubules, D ductules of rhoptries, IN the two inner membranes of the pellicle, OM outer membrane of the pellicle, PR₁/PR₂ preconoidal rings, PR₁/PR₂ ► [polar ring system](#)

25 nm in diameter (Fig. 1). Two accessory structures, the conoidal or preconoidal rings, form an integral part of the conoid and they are connected with each other by a canopy-like membrane. During cell penetration, the conoid protrudes through the anterior ► [polar ring](#) system. The conoid is apparently involved in penetration of host cells. Conoids are found in the motile stages of some ► [Coccidia](#), such as ► [Eimeria](#), ► [Sarcocystis](#), and *Toxoplasma*, but are always absent from the corresponding stages of hemosporidians (e.g., ► [Plasmodium](#)) and ► [piroplasms](#) (► [Babesia](#), ► [Theileria](#)).

Conscutum

Dorsal plate of male ixodid ticks covering the whole backside.

Constipation

Clinical symptom in animals due to parasitic infections (Alimentary System Diseases, ► [Clinical Pathology, Animals](#)).

Contagious Theory

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This theory to explain transmission of infectious diseases is based on the findings of ► [Koch](#), ► [Ross](#), ► [Finlay](#), ► [Simond](#) and others, who showed that bacterial or viral organisms have to be transmitted directly from patient to patient by oral uptake or by bites of blood sucking insects respectively. At the beginning of the era of microbiology it was hard to convince medical authorities (► [Pettenkofer](#) among others) that their old fashioned ► [Miasma-theory](#) is wrong or covers only a few cases.

University (GU), Frankfurt am Main, Germany

General Information

Genus of ascarid ► [Nematodes](#) of the family
Anisakidae (► [Anisakis](#)). Larvae are commonly
found in the intestines, body cavity, and mesen-
teries of a variety of fishes, mainly from marine,
but also from freshwater habitats. Adult parasites
infect the alimentary tract of fish-eating birds
(e.g., *Pelicans*, cormorants) and marine mammals
(e.g., Phocidae, Otariidae).

The parasites' eggs are dispersed within the
feces of the definitive hosts into the surrounding
water column where they hatch. Larvae are then
subsequently transferred along the aquatic food
chain from invertebrates (e.g., copepods, euphau-
siids) to fish in which they grow substantially after
becoming encapsulated in the mesentery.

Similar to other representatives of other
anisakid genera (e.g., *Anisakis*,
Pseudoterranova), *Contraecaecum* contains com-
plexes of cryptic diversity (sibling species).

Clinical Relevance

Contraecaecum osculatum larvae are known as
exciter of the zoonotic Anisakidosis when eaten

alive in raw or insufficiently cooked fish products
(e.g., Sushi, Sashimi).

[Analysis](#) (Wernsdorfer, Vienna), Table 2.

Cooperia

Genus of the nematode family
► [Trichostrongylidae](#). Species of *Cooperia*, live
(as those of the genera *Trichostrongylus* and
Nematodirus) in the small intestine of ruminants.
The adult worms (male 5–8 mm, female
8–11 mm) are rather small, appear reddish, and
are often spiral-shaped. Species are, e.g.,
C. oncophora (cattle), *C. curticei* (sheep/goat).

Disease

► [Cooperiosis](#), ► [Alimentary System Diseases, Ruminants](#).

Therapy

Nematocidal Drugs.

Cooperiosis

Trichstrongylid ► [trematodes](#) of the genus *Cooperia* (► [Trichostrongylidae](#)) live in the upper part of the small intestine of ruminants. The important species include *C. curticei*, which mainly infect sheep and goats, and *C. pectinata*, *C. punctata*, and *C. oncophora*, which mainly infect cattle. *C. oncophora* is less pathogenic for cattle than either *C. pectinata* or *C. punctata*. *C. curticei* is of little pathological significance in sheep. *C. oncophora* only produces pathological lesions in animals experimentally infected with very large numbers of infective larvae (250,000 or more). The lack of pathogenicity is probably explained by the rapid acquisition of resistance by the host, and the superficial character of the intestinal lesions induced. They rather brace or coil themselves among villi to maintain their place. *C. punctata* worms have been reported as penetrating into the mucosa or submucosa. Villous atrophy with reduction in the brush-border enzymes only occurs after heavy infections. Signs of the infection include soft faeces, intermittent or continued ► [diarrhoea](#), progressive emaciation, reduced feed consumption, ► [weight loss](#), and listlessness. There is no ► [anaemia](#). The lack of any significant effect on serum calcium or phosphorus concentrations, or on the skeleton suggest little interference with intestinal absorption. The slight ► [hypoalbuminaemia](#) may, however, indicate macro-molecular leakage into the gastrointestinal tract. Mixed infections with ► *Ostertagia ostertagi* produce severe adverse alterations of the metabolism in calves, which exceed those produced by infection with either

of the species alone. The presence of *C. oncophora* in the small intestine seems to limit the extent of the compensatory digestive responses to *O. ostertagi* infection of the abomasum (► [Alimentary System Diseases, Ruminants](#)).

Therapy

► [Nematocidal Drugs, Animals](#).

Copepoda

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *kope* = hit; *pus*, *podus* = foot.

Geographic Distributions/Epidemiology

Worldwide on fresh and salt water fish.

Morphology/Life Cycle

This group of ectoparasites of fish belongs to the lower ► [crustaceans](#) with the typical **nauplius** larva, which possess one eye and claws (transformed antennae) to attach at the surface of fish (Fig. 1). The anterior ends may also penetrate deeply into the body of fish (Fig. 2). The following families include important parasites:

A. Ergasilidae

The members of this group reach a length of 2–4 mm and are excellent swimmers, so that they may reach easily their host. The females bear large egg sacks. By help of their claws, they become anchored mostly at the

Copepoda, Fig. 1 Diagrammatic representation of a typical *Ergasilus* sp. female (family Ergasilidae). *ES* egg sack

Copepoda, Fig. 2 Diagrammatic representation of the so-called gill maggot *Salmincola salmonea* (family Lernaeidae) being anchored at the gills of a salmon. *B* bulla = adhesion organ, *ES* egg sack, *K* gills, *M1*, *M2* maxillae 1, 2

gills of their host fish (Fig. 1). **Nauplius** larvae hatch from fertilized eggs and reach within 8–10 weeks maturity after passing through further 4 the so-called **copepodit** larvae (Fig. 1), which are free living. The fertilized females attack fish and start a parasitic way of life. One of the most common European species is *Ergasilus sieboldi*, which appears blue on the surface of its hosts.

B. Lernaeidae

The members of this family of parasitic **Crustaceans** appear as 2–30 mm long adults in a slender worm-like shape, so that they are mostly not recognized as crustacean organism (Figs. 3, 4, and 5). By help of an anchor-like anterior end, these slender parasites are fixed in the skin and in the gills of their hosts. They look like sticks at the surface of fish and can only be recognized by their large egg sacks. *Lernaea cyprinacea*, the so-called anchor worm (2.5 cm long), may reach as adults a length of 2 cm. Males and females show a sexual dimorphism: females have a sack- or stick-like body, while the free living males keep their typical copepod shape (Figs. 4 and 5). During the life cycle four nauplius stages occur, followed by one metanauplius and five copepodit stages (some of them suck already blood on a fish host) before the final host is chosen and copulation occurs. Males die afterwards and females stay on the gills of their hosts. So-called salmon-lice (**► *Lepeophtheirus salmonis***) have a life cycle. The adults are able to leave their hosts and to seek another one in crowded ponds.

Symptoms of Disease

A. Ergasilidae

Infections of the gills lead to breathing problems and bleaching of the gills; gills appear bleached and become secondarily infected by bacteria.

B. Lernaeidae

Deep wounds lead to large losses of blood, which weaken the fish and may lead to death (often accompanied by severe bacterial infections).

Copepoda,

Fig. 3 Macrophoto of an Antarctic ice fish (*Macrourus* sp.) with a female of the family Lernaeidae. (a) Surface aspect; (b) Section showing that the parasite has entered the body cavity

Copepoda,

Fig. 4 Diagrammatic representation of a female lernaeid copepod. *AN* anchor, *ES* egg sack

Diagnosis

Macroscopical inspections of the fish show the attached worms; at places several spots of infections may be seen.

Infection

Swimming parasitic stages (mostly females) attach themselves at the skin and/or gills.

Prophylaxis

Avoid use of unfiltered pond water; use quarantine methods for new fish before entering them into a

Copepoda,

Fig. 5 Macrophoto of a fish with the so-called stick-disease. Two lernaeid adult crustaceans are anchored at the skin of their host

pond/aquarium. Microscopical inspection of skin scapes.

Incubation Period

Several weeks.

Prepatent Period

Several weeks.

Patency

Weeks to years.

Therapy

Very difficult; Masoten[®] (3 g/ha water-surface) was successful as well as ivermectin dotated food.

Copepodit

Invasive larvae of [► Copepoda](#) ([► Lepeophtheirus salmonis](#)).

Copra's Itch

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Allergic skin disease due to [► Acarus siro](#), [► mites](#).

Coproantigen

From Greek: *kopros* = faeces; DNA – material of parasites that is excreted within the host's faeces.

Coprophagous Host

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes beetles, earthworms, cockroaches, and other animals, which feed feces of

vertebrates and thus ingest potentially larvae or eggs of worms. Inside their body a further development (e.g., to larva 3) may occur or stages are just stored until the final host ingests this coprophagous host. In case of a development inside this host, it is considered either as intermediate host or as transport host.

Coproscopy

Microscopical analysis (Greek: *skopein* = look at) of the faeces of hosts to diagnose parasitic stages.

Coracidium

Swimming larva of pseudophyllidean ► [tape-worms](#) provided with ► [cilia](#) and centrally bearing a hooked ► [oncosphaera](#) larva.

Cordylobia

Genus of the fly family Calliphoridae. *C. anthropophaga* – the so-called ► [tumbu fly](#) (Figs. 1 and 2) causes the boil-like (furuncular) type of myiasis like that produced by ► [Dermatobia hominis](#). These flies occur in Continental Africa, South of the Sahara. *C. rodhaini* is a related species (called Lund's fly), which infects humans much less frequently than *C. anthropophaga*.

1. *C. anthropophaga*, the Tumbu fly of continental Africa south of the Sahara. The eggs are laid in batches of 200–300 on dry, shaded ground.

Cordylobia, Fig. 1 *Cordylobia anthropophaga*, adult

Cordylobia, Fig. 2 *Cordylobia anthropophaga*, larva

2. *C. rodhaini* is found in the moister parts of tropical Africa in Central Africa.
3. *C. ruandae*, these flies attack humans as well as animals and lead to myiasis. Inside the skin of the host the development takes 8–15 days, before the larvae 3 emerge, fall to the ground, and pupate. Often up to 50 larvae may be found within one host.
4. The symptoms of an infection are similar to those of *Dermatobia hominis*.

Cotylurus Species

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

These species are digenean (Strigeatida) parasites of the intestine of waterfowls and related species (ducks, geese). First intermediate hosts are water molluscs. The emerging cercariae penetrate water invertebrates (leeches, molluscs), where they transform to metacercariae that are infectious for their final hosts. The adults reach a length of up to 2 cm, possess two suckers, and are covered by tegumental spines.

Species

- *C. cornutus* in many waterbirds in Europe, Asia, Africa, and America.
- *C. japonicus* in Asia; also human cases had been found.
- *C. pileatus* in seagulls and related species in Europe and Asia.
- *C. tardus* in ducks and geese in Europe and North America.

Coxa

Basal segment of the legs in insect and ticks, by means of which legs are attached to the ventral body side.

Coxal Glands

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: *coxa* = hip.

Glands of nymphal and adult stages of, e.g., argasid ► [ticks](#) (situated between coxae I and II), which excrete the fluid of blood meals thus retaining in the intestine mainly the blood cells. Due to this excretion, agents of diseases may be mechanically transmitted from one host to another.

Coxiella burneti

Rickettsial bacteria which are transmitted by *Dermacentor* and *Amblyomma* ticks introducing the so-called Q-fever of cattle, sheep, humans, and other hosts in Queensland (Australia).

Crab Louse

► [Lice](#) (*Phthirus pubis*).

Crataerina pallida

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This louse fly species (family ► [Hippoboscidae](#)) parasitizes on swallows and related birds. The specimens reach a length of only 3–4.5 mm, possess wings, but are unable to fly. The abdomen of sucked specimens appears greenish (due to ingested, gleaming blood). Occurrence in all regions of swallows.

Craterostomum

Genus of small strongylid nematodes in horses.

Creeping Eruption

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

This term describes moving skin swellings. This symptom of visible wandering swellings of human skin is induced mainly by larvae 3 of hookworms (► *Ancylostoma*, Fig. 1a, b), but also by tapeworm larvae (*Spargana*), cercariae of ► *Schistosoma* species as well as by larvae of some flies. In general, these larvae belong to species, which do not reach maturity in humans (since their final hosts are animals). Therefore,

they remain motile only for a while and finally will be killed by the activities of the human immune system. Wandering larvae of the human filarial worm ► *Loa loa* and ► *Mansonella perstans* produce even larger swellings (named Calabar swellings). However, they disappear after an initial growing and become mature. Then they may appear in eyes without larger swelling reactions. Larvae of the nematode ► *Strongyloides stercoralis* which enter the human body immediately after they had been excreted within feces (► [autoinfection](#)) have developed the highest wandering speed reaching 10 cm per hour and thus are called “larva currens.”

Prophylaxis

In any case, avoid contact with human or animal feces.

Therapy

The therapy is rather difficult. It is recommended to cover infected skin regions with ice and to

Creeping Eruption,

Fig. 1 (a, b) Foot and arm of a patient showing creeping larvae inside skin deriving from infections with the dog's hookworm ► *Ancylostoma caninum*

apply topically a 15 % thiabendazole cream. The oral application of albendazole or mebendazole must be done for 10–15 days, while in case of ivermectin mostly a single dose is efficient. However, none of these medicaments are officially registered for human use. Furthermore, in order to avoid allergic reactions and/or anaphylactic shock, antihistaminic drugs should be applied additionally.

Furthermore see ► *Loa loa*, ► *Strongyloides stercoralis*, ► *Ancylostoma caninum*, *A. braziliense*, *Uncinaria stenocephala*.

Crenosoma vulpis and Other Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek, *soma* = body. Latin, *crenatus* = with notches; *vulpes* = fox. English, lungworm of canids.

Geographic Distribution/Epidemiology

Europe, Asia, and North America with prevalence rates of 0.4 %. Related *Crenosoma* species (e.g., *C. goblei* in racoons, *C. melesi* in badgers, *C. vulpis* in foxes, and *C. striatum* in hedgehogs) reach prevalence rates up to 40 % in their final hosts.

Morphology/Life Cycle

The adult male worms reach a length of 5–7 mm, while female worms measure 12–16 mm and have

a width of 0.35 mm. They appear as tiny whitish-reddish filaments in the bronchia and trachea of their final hosts (foxes, dogs, and relatives). Characteristics are the cross striation of the cuticle at the apical pole and overlapping cuticular folds. The females are oviparous and the larva containing eggs measures $70 \times 36 \mu\text{m}$. The larvae 1 (250–330 μm long) are excreted with the feces, since they hatch already in the trachea and are swallowed when mucus is transported in the mouth. Outside of the body, the larva 1 enters snails of the genera *Agriolimax*, *Arion*, *Cepaea*, *Succinea*, etc., where they grow up within 8–10 days (via two molts) into the infectious larva 3. If final hosts ingest such snails, the larvae enter their intestinal wall and reach via bloodstream or via peritoneal cavity of the lungs, where maturity is reached within 8–14 days (Fig. 1).

Crenosoma vulpis and Other Species, Fig. 1 Light micrograph of the hatching larva 1 of *Crenosoma striatum*. See worm eggs, hedgehog

Symptoms of Disease

Chronic coughing, breathing problems, eosinophilia, bronchiolitis, pneumonia, and anemia. In slight infections, such symptoms may lack, but fitness of the hosts is considerably reduced.

Diagnosis

Determination of larvae in feces or in saliva by help of the Baermann technique.

Infection

Oral uptake of infected intermediate hosts (snails).

Prophylaxis

Difficult or nearly impossible since free roaming final hosts may ingest everywhere the infected snails.

Incubation Period

C. vulpis, 11–14 days.

Prepatent Period

3 weeks.

Patency

About 10–12 months.

Therapy

Fenbendazole (50 mg/kg bodyweight for 3 days, oral), milbemycin oxime (oral, 1 × 0.5 mg/kg bodyweight), or moxidectin (2.5 mg/kg bodyweight, topically).

Crepidostomum

Genus of flukes, ► [Digenea](#).

Crepidostomum farionis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *crepidula* = small shell; Greek: *stoma* = mouth; Latin: *fario* = trout.

Trematode species (2–6 mm × 1.5 mm) inside the intestine of fresh water fish (trouts, salmons). First intermediate hosts are mussels; second intermediate hosts: larvae of ephemeropterid flies or leeches (*Sanguinicola*). Egg size: 65–85 µm × 40–44 µm; they can be diagnosed by microscopic analyses. Treatment by means of Tremazol® (praziquantel) dropped into the aquarium. Treatment of food fish: 1 × 5 mg Praziquantel/kg bodyweight via dry food.

Crista

There are several meanings:

- Crista sterni: Place of attachment of flight muscles at the breast of birds.
- Type of infolding of the inner membrane of ► [mitochondria](#).
- Comb-like structures.

Cristae

This is the number for infoldings (single: crista), the inner membrane of some mitochondria at the surface of which the ► [TCA cycle](#) is anchored. For example, erythrocytic stages of avian malarial

parasites (such as *Plasmodium lophurae*) are cristate, while those of rodent and most other mammalian *Plasmodium* spp. are acristate. Asexual stages of *P. falciparum* have a single acristate mitochondrion, which apparently gives rise during the formation of gamonts (gametocytes, ► [Kinete](#), Fig. 3) to several cristate ones. This fact suggests, that there is apparently a metabolic change. The mitochondria of the gamonts of the piroplasms remain, however, acristate (Gametes) as are the trypanosomal mitochondrion in the region of the ► [kinetoplast](#) (TAC). Energy metabolism, ► [Kinete](#), Fig. 3.

Other types of mitochondrial infoldings are tubuli (e.g., Gametes, Figs. 1 and 2A) or – if those are enlarged – they are named sacculi.

For further information see ► [Energy Metabolism](#).

Crithidia mellificae

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

An acidophilic trypanosomatid of honey bees, occasionally erroneously mixed with ► [Malphighamoeba mellificae](#).

Crithidia oncopelti

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This species is one of the exceptions among the trypanosomatid parasites, since its flagellum does not contain the typical ► [paraxial rod](#).

Crowding Effect

Blocking of development of individual parasites due to overcrowding of a habitat.

Crura

Apart from aspidobothreans (and a few other exceptions) the intestine of ► [Platyhelminthes](#) divides after the esophagus into two lateral terminally closed branches = crura (► [Digenea](#), Fig. 6, ► [Platyhelminthes/Intestine and Food Uptake](#)).

Crust

Clinical and pathological symptoms of infections with skin parasites (► [Skin Diseases, Animals](#), ► [Ectoparasites: New Approaches](#)).

Crustacea

Classification

Class of ► [Arthropoda](#).

General Information

The crustaceans were termed with respect to their often very strong chitinous ► [cuticle](#), which is strengthened in comparison to that of insects by the inclusion of calcium salts; thus growth can only proceed after repeated molts. The heteronomously segmented ► [dioecious](#) Crustacea appear in a great variety, although lower

(former: Entomostraca) and higher (Malacostraca) groups can be clearly differentiated according to their larvae (► [nauplius](#) or zoea). Common to all crustaceans are the following features:

- They have two pairs of antennae (possibly of different size).
- The uptake of O₂ occurs by means of inner or outer gills.
- A pair of mandibles and two pairs of maxillae act as mouthparts. They are located ventrally at the head, which is often closely connected to the thorax (► [Cephalothorax](#)) and covered dorsally by a carapax in some groups.
- Each of the heteronomous body segments is ventrally provided with a pair of extremities, which appear as maxillipodia, pereopodia, or pleopodia (depending on their location along the body).
- These extremities show a typical biramous organization and are composed of an inner endopodite and an outer exopodite.
- Eyes of the compound type are situated, if present, dorsally on stalks; eyes of the median type (e.g., nauplius eye) are composed of three or four small pigment-cup ocelli of the inverse form.
- The circulatory system is open, involving a dorsally located heart (in thorax or abdomen).
- Antennal or maxillary nephridial glands work as an excretory system supported by different cells (nephrocytes) opening at the body's surface.
- The development occurs in general as a ► [metamorphosis](#) involving different larval stages (nauplius or zoea) and growth by repeated molts.

System

The following taxa include some parasitic forms, although most members of the Crustacea are free-living:

Crustacea, Table 1 Some common parasitic crustaceans

Subclass, order/ species	Length (mm)	Host/habitat	Transmitted pathogens
Branchiura			
<i>A. coregoni</i>	10–15	Salmonids/skin	Fungi, bacteria (<i>Pseudomonas punctata</i>)
<i>Argulus foliaceus</i>	m 8–10 f 15	Many fish, amphibian species/skin, gills	Fungi, bacteria (<i>Pseudomonas punctata</i>)
Cirripedia			
<i>Sacculina carcini</i>	20–40	Crabs/inner organs	–
Copepoda			
<i>Caligus elongatus</i>	7	Salmonids/skin, gills	–
<i>Clavella adunca</i>	f 4	Marine fish/skin	–
<i>Cyclops</i> spp.	up to 3	Free-living	Larvae of cestodes and nematodes
<i>E. gibbus</i>	1.0	Eels/skin, gills	–
<i>Ergasilus sieboldi</i>	1.7	Freshwater fish/gills	Fungi, bacteria
<i>Lepeophtheirus salmonis</i>	10	Salmonids/skin	–
<i>Lernaeocera branchialis</i>	m 1.5 f up to 60	Marine fish/gills	–
<i>Penella balaenoptera</i>	300	Whales/skin	–
<i>Salmincola</i> spp.	1–1.5	Salmonids/skin	–
<i>Sarcotaces arcticus</i>	m 2 f 25	Marine fish/skin	–
Isopoda			
<i>Aega psora</i>	50	Marine fish/skin	–
<i>Anilocra physodes</i>	20	Marine fish/skin	–
<i>Cirolana borealis</i>	30	Marine fish/skin	–

m male, f female

- Class: Crustacea
 - Subclass: Ostracoda (some species are parasitic on gills of fish)
 - Subclass: ► **Copepoda** (some are ectoparasites of fish, some are intermediate hosts for ► **Cestodes** and ► **Nematodes**)
 - Subclass: ► **Branchiura** (some species are blood suckers on fish, thus named fish lice, ► **Argulus**)
 - Subclass: ► **Cirripedia** (some species are endoparasites in marine crabs)
 - Subclass: Malacostraca (higher Crustacea)
 - Order: Amphipoda (free-living, some are intermediate hosts for endoparasites)
 - Order: ► **Isopoda** (some species are ectoparasites of fish)
 - Order: Decapoda (many species are intermediate hosts for endoparasites)

Important Species

Table 1.

Life Cycle

► *Lepeophtheirus salmonis*.

Integument

The cuticle of the crustaceans is constructed according to the same plan as in ► [Ticks](#), ► [Mites](#) and ► [Insects](#). However, in crustaceans minerals such as CaCO_3 and $\text{Ca}_3(\text{PO}_4)_2$ may occur additionally, thus leading to a further hardening of the cuticular exoskeleton (needed, e.g., to overwhelm high water pressures). The molt (► [Ecdysis](#)) in crustaceans occurs due to activity of hormones such as in other arthropods. Here the so-called Y-organs are steered by neurohormones. ► [Ecdysis](#) starts in Crustacea when the excretion of the molt-inhibiting hormone (MIH) is stopped and the Y-organs produce ► [crustecdyson](#) (► [Ecdysteroids](#)).

Nervous System

The nervous system shows trends towards concentrations at the anterior pole to form a large brain and in the thoracic region, where a large thoracic ganglion is formed by fusion of segmental ganglia during evolution. In the highly aberrant body shapes of the parasitic crustaceans many variations of the nervous system occur.

Crustecdyson

Hormone that induces molt in higher ► [Crustacea](#) (Malacostraca) within the so-called Y-organ (= carapax gland).

Cryptobia

Genus of Kinetoplastea (phylum Euglenozoa). The two-flagellated members of the different species are either ectoparasites on the body surface or endoparasites in the digestive tract or in the blood

of fish. *C. branchialis* is found on the gills of crabs and other cyprinids reaching a length of 10–20 μm . *C. salmositica* occurs in salmonid fish in Western and Northern America in the blood and on the gills. An attenuated strain has been produced and is routinely used as an experimental live vaccine, which protects fish for up to 2 years. *Cryptobia* (syn. ► [Trypanoplasma](#)) *iubilans* was described as an intracellular parasite in cichlid ornamental fish to destroy portions of the intestine liver and/or spleen.

Cryptocaryon irritans

Name

Greek: *cryptos* = hidden, *karyon* = nucleus, Latin: *irritare* = disturb.

The life cycle of this ciliate which parasitizes on/in the skin of marine fish is similar to that of ► [Ichthyophthirius](#), although it belongs to another group of ciliates. The trophozoites inside skin are only 0.5 mm in diameter. The macronucleus is only badly seen and appears as white dots in higher magnification (Fig. 1). The fish appears with white dots and may die due to heavy infections.

Cryptocaryon irritans, Fig. 1 Trophozoite of *Cryptocaryon irritans* in the skin of a tropical fish

Cryptocotylepis

Cryptomitosis

► **Nuclear Division** occurring in most parasitic protozoans during which the nuclear membranes are retained.

Cryptosporidial Relations

The genus is more closely related to the ► **gregarines** than to true ► **Coccidia**. This was shown by phylogenetic analysis of apicomplexan parasites inferred using small-subunit ribosomal RNA gene sequence. These findings may explain why *Cryptosporidium* stages are not sensible to drugs which affect a broad spectrum of coccidians.

Cryptosporidiosis, Animals

Pathology

Cryptosporidiosis is an important infectious disease affecting mucosal surfaces commonly found in snakes, lizards, birds, and mammals.

► *Cryptosporidium* spp. have been reported in all domestic animals including cats, dogs, and pigs. In horses, symptoms have been particularly observed in animals with inherited or acquired immunodeficiency. Cryptosporidiosis is economically most significant in calves and lambs. Symptoms are: enterocolitis in newborn animals manifested by ► **diarrhoea** of variable severity; signs of depression, ► **anorexia**, and ► **weight loss** are also seen. The most prominent lesions occur in the ileum. They include blunting and some fusion of villi, and hypertrophy of the crypts of Lieberkühn. There are great individual variations in clinical reactions to *Cryptosporidium* infection and controversy exists as to whether the parasite occurs as a primary pathogen or whether it causes disease by interacting with other enteropathogens.

Immune Responses

As the replication and development of the parasite is confined to mucosal surfaces, local immune functions of the mucosa-associated lymphoid tissue (► **MALT**) are of special importance. Interest in the nature of these host responses is heightened by a unique feature of the parasite's development. Merozoites reside intracellularly in epithelial cells and remain anchored at the luminal surface segregated from the host cell ► **cytoplasm**. Since *C. parvum* infections of animals are generally found in neonates and refractoriness to infection develops 2–3 weeks after birth, most investigations on the immune responses have been performed in suckling or immunocompromised mice. Some studies have been alternatively performed with *C. muris* which is able to infect adult immunocompetent mice.

Innate Immunity

As with other coccidian, e.g., *T. gondii*, macrophage activation by IFN- γ leads to partial control of microbial reproduction. In T cell deficient individuals such as ► **AIDS** patients or nude or SCID

mice a ► **chronic infection** characterized by gradual expansion of inflammatory foci develops, which in the case of immunodeficient mice eventually results in ► **morbidity** and death. Several studies, however, have demonstrated the existence of partially protective innate immune mechanisms mediated by IFN- γ . Treatment of SCID mice with anti-IFN- γ or anti-IL-12 antibodies increased susceptibility to infection and reduced the time till death from >12 to 5–6 weeks. Although cryptosporidium sporozoites or ► **oocyst** antigen preparations enhanced IFN- γ production by splenic NK cells in vitro, treatment of mice with anti-ASGM1 antibodies to deplete NK cells had no effect on susceptibility to infection. In other experiments *C. parvum* infection of SCID mice was not influenced by IL-2 treatment which activates NK cells. Thus, the in vivo data on the role of NK cell activation conflict with the in vitro findings. Obviously, the cell type in the mucosa which produces IFN- γ in the absence of T cells still has to be identified. Likewise, the accessory cells involved in the local inflammatory response have also to be identified, since the gut epithelium contains only few macrophages.

B Cells and Antibodies

Different subclasses of parasite-specific Igs increase in serum and mucosal secretions during *C. parvum* infections of humans and animals and IgG titers especially may persist for up to several years post-infection. Coproantibody titers of IgA and IgM increase during infection and decrease after resolution of the disease. The antibodies produced recognize a number of immunodominant ► **sporozoite** antigens of approximately 11, 15, 20/23, 44, 100, 180, and >200 kDa. Different antibodies induced by immunizations possess protective capacity as shown by (1) inhibiting the *C. parvum* development in vitro or in suckling mice by administering antibodies orally or by (2) effectively attenuating the clinical symptoms of human cryptosporidiosis by treating immunocompromised patients with hyperimmune bovine colostrum containing high concentrations of anti-cryptosporidia antibodies. Some of the antigens recognized by protective antibodies have been molecularly cloned, but the

exact localization and characterization of the function of these proteins awaits further studies.

Although antibodies induced by immunization with antigens could inhibit parasite development, there is considerable doubt about the protective role of antibodies during natural infection. AIDS patients with severe cryptosporidiosis have high titers of *C. parvum*-specific secretory IgA. Furthermore, depletion of B cells in neonatal mice by anti- μ chain treatment, did not alter the ability to control cryptosporidiosis. On the other hand, breast-fed babies are less likely to experience cryptosporidiosis while patients with congenital hypogammaglobulinemia sometimes develop chronic cryptosporidiosis.

T Cells

C. parvum induces inflammatory infiltrates in the lamina propria of the gut containing lymphocytes, macrophages, and plasma cells. In the Peyer's patches of mice increased numbers of CD4⁺ and CD8⁺ cells were found and purified T cells from spleens of infected animals showed a proliferative response towards parasite antigens. A parasite-specific delayed type hypersensitivity (DTH) can be elicited in *C. parvum*-infected rats by oocyst antigen injection. The functional importance of a specific T cell immune response was demonstrated by the increased pathology villus atrophy, crypt ► **hyperplasia**, erosions of gut epithelium found in T cell-deficient hosts such as nude rats and mice, SCID mice, as well as, in normal mice depleted of T cells by administration of anti-T cell antibodies. In studies with *C. muris*, ► **chronic infections** in T cell-deficient mice developed similar pathology to those found in immunocompromised patients with cryptosporidiosis. In neonatal mice $\gamma\delta$ as well as $\alpha\beta$ TCR-expressing T cells are both involved in immunity against *C. parvum* while in adult animals the infection appears mainly to be controlled by $\alpha\beta$ T cells. Clinical studies of human cryptosporidiosis in HIV patients and experiments with mice, both, indicated that CD4⁺ T cells are the major players in host protection. Susceptibility to and severity of *C. parvum* infection increases with the decrease of CD4⁺ cell counts in AIDS patients. In mice the continuous administration of anti-

CD4 antibodies allowed chronic *C. parvum* infection to develop. The protective effect of lymphocyte transfer to SCID mice is abrogated by the depletion of CD4⁺ cells. In contrast to the dominant role of CD4⁺ T cells, CD8⁺ cells play a negligible role as shown by cell depletion experiments in vivo or by using mice deficient for MHC class I expression. Only some investigators reported a small increase in oocyst production and/or a prolongation of patent infection as a result of treatment of mice with anti-CD8 antibodies. Using intraepithelial lymphocytes (IELs) from immune donor mice to adoptively transfer protection it was found that also in this cell population the CD4⁺ subpopulation is the most effective.

One of the most important effector molecules produced by protective T cells is IFN- γ as shown by enhanced susceptibility of mice as a consequence of treatment with IFN- γ -neutralizing antibodies. Production of this cytokine by IELs was found to be upregulated during the course of infection. However, IFN- γ -independent mechanisms of immunity may also exist, since mice continuously treated with anti-IFN- γ antibodies nevertheless eventually overcome the infection with *Cryptosporidia*. In line with this, mouse-strain-dependent differences in susceptibility to infection (BALB/b versus BALB/c mice) were not linked to differences in IFN- γ production.

The mechanisms by which IFN- γ mediates control of the parasite remain to be determined. Treatment of mice with inhibitors of ► [nitric oxide](#) production did not influence reproduction of *C. parvum*, unlike the effects found in other experimental infections with parasites such as ► [Leishmania](#). Alternatively, documented IFN- γ effects such as enhancement of the production of the secretory component of IgA or the enhancement of the respiratory burst may be operative in the IFN- γ -mediated control of *Cryptosporidium* infection. IL-12 appears to be critically involved in the upregulation of IFN- γ production as shown by treatment of newborn mice with anti-IL-12 antibodies resulting in enhanced disease susceptibility. Another cytokine involved in the protective immune mechanisms may be IL-2 since treatment of mice with anti-IL-2 increased oocyst

production and in a human study IL-2 therapy resulted in less severe diarrhea and oocyst shedding in AIDS patients.

Recently, a protective role of Th2 cytokines in cryptosporidial infection has been reported. Although the amounts of IL-4 or IL-5 produced during the infection appear to be low, treatment of mice with anti-IL-4 or anti-IL-5 antibodies, especially when both were combined, increased oocyst shedding. In addition, adult IL-4-deficient mice excreted oocysts in feces approximately 23 days longer than control mice. Mast cells or eosinophils as effector cells stimulated by these cytokines are unlikely since these cells were not found in significant numbers by histopathological observation in the epithelial infiltrates and mast-cell-deficient mice were not significantly more susceptible to infection than control mice. Other studies, however, suggest that overproduction of IL-4 might correlate with increased susceptibility to infection. BALB/b mice produced significantly more IL-4 than the less susceptible BALB/c mice and onset of recovery in BALB/b mice coincided with a reduction of IL-4 production.

Cryptosporidiosis, Man

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The coccidium *Cryptosporidium parvum*, the oocysts of which are 4–5 μ m in diameter,

containing four sporozoites, parasitizes the microvillar border of the intestinal epithelial cells projecting into the lumen. With heavy infections the bile ducts, trachea, and possibly conjunctive may also be involved. In addition to the regular coccidian cycle, thin-walled oocysts are formed that sporulate in the intestine and are a source of ► [superinfection](#); the thick-walled oocysts pass to the outside and develop four sporozoites. In healthy volunteers, acute infection can be produced by ingestion of 30–300 or more oocysts accompanied by ► [abdominal pain](#), cramps, diarrhea, and fever lasting for 3–10 days.

C. parvum causes debilitating gastrointestinal illness in humans and other mammals and is a frequent opportunistic pathogen in ► [AIDS](#) patients. ► [Chronic infection](#) in immunosuppressed patients is associated with flattened villi, resulting from loss of epithelial cells and lack of regeneration (pathology/ Fig. 6A). This is accompanied by often copious and frequent diarrhea, malabsorption, and ► [weight loss](#). Both the light and evanescent infections in the immunocompetent and the heavy infections in the immunosuppressed show little inflammatory reaction. As studied in experimental animals, developing immunity is accompanied by the infiltration of lymphocytes into the lamina propria.

Main Clinical Symptoms

Abdominal pain, heavy ► [diarrhea](#) (*in immuno-compromised persons*).

Incubation Period

One to two days.

Prepatent Period

Two to four days.

Patent Period

Twelve to fourteen days.

Diagnosis

Microscopic determination of oocysts in fecal samples (Ziehl-Neelsen stain), *Cryptosporidium* species/Figs. 1–6.

Prophylaxis

Avoid contact with human or animal feces.

Therapy

Treatment see ► [Coccidiocidal Drugs](#) and ► [Treatment of Opportunistic Agents](#).

Cryptosporidium andersoni

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species is one of the recent 30 valid *Cryptosporidium* species. It occurs, e.g., in bovines and camels and was previously considered as group of *C. muris*, although there is in general only low-graded host specificity in *Cryptosporidium* species.

Classification

Genus of ► **Coccidia** (of the subphylum Apicomplexa).

General Information

Name

Greek: *kryptos*, hidden; *spora*, seed.

The species of this genus are very small (Table 1) and were known since more than 100 years within diarrheic feces of young animals. They obtained

Cryptosporidium Species, Table 1 Valid species of the genus *Cryptosporidium*. *Cryptosporidium* species and their association with clinical disease

<i>Cryptosporidium</i> species and genotypes	Mean oocyst dimensions (μm)	Major host(s)	Association with human cryptosporidiosis	Association with animal cryptosporidiosis
<i>C. andersoni</i>	7.4 × 5.5	Cattle	Rarely associated	Usually seen in yearlings and adult cattle
<i>C. baileyi</i>	6.2 × 4.6	Chickens, other birds	No association	Severe outbreaks in poultry
<i>C. bovis</i> (previously bovine B genotype)	4.9 × 4.6	Cattle	Rarely associated	Shedding is seen mainly in weaned and sometimes pre-weaning calves
<i>C. canis</i> (previously dog genotype)	5.0 × 4.7	Dog	Occasional sporadic cases in various, especially nonindustrialized countries	In puppies
<i>C. cuniculus</i> (previously rabbit genotype)	5.6 × 5.4	Rabbit, humans	Occasional, seasonal sporadic cases in the UK, France, and Nigeria	Asymptomatic shedding in rabbits
<i>C. fayeri</i> (Previously marsupial genotype I)	4.9 × 4.3	Marsupials	Rarely associated	Oocyst shedding is not associated with diarrhea
<i>C. felis</i>	4.6 × 4.0	Cat	Occasional sporadic cases in various countries	More common in kittens
<i>C. fragile</i>	6.2 × 5.5	Black-spined toad	No association	Infection appears to be host specific
<i>C. galli</i>	8.3 × 6.3	Chicken	No association	Shedding can be prolonged
<i>C. hominis</i> (previously referred to as <i>C. parvum</i> human genotype, genotype I, and genotype H)	4.9 × 5.2	Humans	Common cause of diarrheal disease in sporadic cases and in outbreaks	There is no defined animal host for this species
<i>C. macropodum</i> (previously marsupial genotype II)	5.4 × 4.9	Eastern gray kangaroo	No association	Infection is limited to marsupials

(continued)

Cryptosporidium Species, Table 1 (continued)

<i>Cryptosporidium</i> species and genotypes	Mean oocyst dimensions (µm)	Major host(s)	Association with human cryptosporidiosis	Association with animal cryptosporidiosis
<i>C. meleagridis</i>	5.2 × 4.6	Homeothermic birds; mammals	Sporadic cases are reported more frequently in some populations, for example infections are as common as for <i>C. parvum</i>	Associated with enteritis, diarrhea and death in birds
<i>C. molnari</i>	4.7 × 4.5	Sea bream	No association	Infection is seasonal
<i>C. muris</i>	7.0 × 5.0	Rodents	Rarely associated	Oocyst shedding has been reported in other animal species, too
<i>C. parvum</i> (also sometimes previously called bovine genotype II, and genotype B)	5.0 × 4.5	Humans, mammals	Common in sporadic cases and outbreaks; zoonotic transmission, either directly animal to person through recreational or occupational farm animal contact (especially young ruminants) or indirectly through contaminated drinking water	Common cause of diarrhea in pre-weaning calves, lambs, and goats; infection can be fatal
<i>C. ryanae</i> (previously deer-like genotype)	3.7 × 3.2	Cattle	No association	Infection is host specific
<i>C. scophthalmi</i>	4.4 × 3.9	Turbot	No association	In younger fish
<i>C. scrofarum</i> (previously pig genotype II)	5.2 × 4.8	Pig	Rarely associated	Infection is seen in pigs aged more than 6 weeks
<i>C. serpentis</i>	6.2 × 5.3	Reptiles	No association	Infection is common in snakes and in lizards but only fatal in snakes
<i>C. suis</i> (previously pig genotype I)	4.6 × 4.2	Pig	Rarely associated	Infection is usually seen in pre-weaning pigs
<i>C. tyzzeri</i> (previously mouse genotype I)	4.6 × 4.2	Mice	Rarely associated	Infection is usually most intense in the ileum
<i>C. ubiquitum</i> (previously cervine genotype)	5.0 × 4.7	Various mammals	Sporadic cases in various countries	Broad host range and a common parasite of weaned lambs
<i>C. viatorum</i>	5.4 × 4.7	Humans	Sporadic cases	No animal host is known
<i>C. varanii</i> (syn. <i>C. saurophilum</i>)	4.8 × 4.7	Reptiles	No association	Infection is seen in lizards and snakes
<i>C. wrairi</i>	5.4 × 4.6	Guinea pig	No association	Disease not described
<i>C. xiaoi</i> (previously <i>Cryptosporidium bovis</i> -like genotype or <i>C. bovis</i> from sheep)	3.9 × 3.4	Sheep	No association	In sheep, in goats
Chipmunk genotype I	Not reported	Chipmunk	Rarely associated	No association
Horse genotype	4.6 × 4.2	Horses	Rarely associated	No association

Skunk genotype	Not reported	Skunk	Rarely associated	No association

For species names, see the table above which is taken in parts from the paper of Chalmers RM and Katzer F (2013) Looking for *Cryptosporidium*: The application of advances in detection and diagnosis. Trends Parasitol 29:231–251.

Cryptosporidium Species, Fig. 1 Life cycle of *Cryptosporidium parvum*. Species determination is still confusing

as some authors believe in two species (*C. parvum*, *C. muris*), each parasitizing a wide range of mammals.

Cryptosporidium Species, Fig. 2 LM of oocysts of *Cryptosporidium parvum*

importance as important ► [opportunistic agents](#) in AIDS patients. In *C. parvum* several genotypes occur: one is pathogenous for humans, one for calves, and another for pigs and man. Cryptosporidia are peculiar, since they are attached by a so-called feeder organelle to the surface of their host cells (like some ► [gregarines](#)), have only a few tubular ► [mitochondria](#), and are not susceptible to any known antiparasitic drug. The wall of the ► [oocyst](#) apparently develops into that of the ► [sporocyst](#). This may explain the observation of thin- and thick-shelled oocysts. Recent molecular biological studies showed that *Cryptosporidium* spp. are closely related to gregarines. Although *Cryptosporidium* spp. possess the organelles of other coccidians, a typical mitochondrion is lacking. However, a similar organelle, but without genome, is present (Figs. 1, 2, 3, 4, 5, and 6).

Cryptosporidium Species, Fig. 1 (continued) Cross-transmission experiments by Göbel, however, indicate that there is only a single nonhost-specific species in mammals. Differences in pathogenicity depend on passages in different hosts. *Cryptosporidium parvum* is important, since infections in immunocompromised humans (e.g., ► [AIDS](#) patients) are often fatal due to permanent endo-autoinfections (14), opportunistic agent 1. The first infection of mammalian hosts occurs by ingestion of sporocysts (16) containing four sporozoites (1). The latter are set free in the small intestine when the sporocyst wall is ruptured along its suture. 2–7 From the interpretation of electron micrographs, it appears that the ► [sporozoite](#) becomes attached to the ► [microvilli](#) of a gut cell and grows to form a ► [schizont](#) with an inner vacuole (2; *V*). This vacuole is enlarged (3) and the nucleus divides twice (4). During the next ► [nuclear division](#), (5) 8 merozoites (6) are produced and are set free (7). These merozoites may become attached to noninfected epithelial cells (2) and repeat the schizogonic process (2–7). 9–11 Formation of gametes: some merozoites start the formation of multinucleate microgamonts and up to 16 nonflagellated ► [microgametes](#) (10), which fertilize macrogametes (11) that had developed via macrogamonts from other

merozoites (7). The ► [zygote](#) (12, 13) may follow two different ways of development. 15a, 16a Endo-autoinfection: the oocyst sporulates on its host cell and releases the 4 sporozoites, leading to an increasing ► [auto-infection](#) (important for immunosuppressed hosts including man). Such oocysts may also sporulate inside the intestine but do not release their sporozoites (13–16). In this case they are excreted with the feces. During the ► [sporulation](#) process, a sporocyst wall is formed around the four sporozoites, replacing the apparently smooth and rupturing oocyst wall, so that the stages found in feces are sporocysts. This interpretation is supported by the occurrence of a peculiar suture of the wall, which is known from sporocyst walls of other ► [coccidia](#). Oocysts (13) may also be excreted unsporulated and then form their inner sporocyst wall and four sporozoites outside their host. The resulting sporocysts are as infectious to the range of host animals as the sporocysts excreted in sporulated form or the oocysts obtained by scraping the host's mucosa. *FO* attachment zone, ► [feeder organelle](#), *HC* host cell, *N* nucleus, *NH* nucleus of host cell, *OW* oocyst wall, *RB* residual body, *S* schizont, *SP* sporozoite, *V* inner vacuole (for further species see Table 1)

Cryptosporidium Species Phylogenetic Origin

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

According to the phylogenetic tree established by Mogi and Kita (2010), *Cryptosporidium* species

are closely related to ► [gregarines](#). This is also underlined by the fact that *Cryptosporidium* species do not enter host cells (but are only attached by typical anticoccidial drugs. Furthermore they possess additionally alternative oxidase (AOX) and a pyruvate-NADP-oxireductase besides the malate-quinone-oxireductase of *Plasmodium* species and *Toxoplasma gondii*.

Crystalloid Body

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This structure appears in electron microscopy as compact globules of several micrometers (µm) in diameter consisting of electron-dense particles arranged in a honeycomb-like pattern. The size of these particles varies depending on the species. In the hemogregarine *Karyolysus*, they measure 35–50 nm in diameter, in ► *Cystoisospora* only 30 nm, in *Cryptosporidium* they reach 16–35 nm, and in *Plasmodium* ookinetes and oocysts they measure about 43 nm and occur at several places (Figs. 2 and 3 in ► *Kinetes*). The functional role of the crystalloid bodies is still unknown, although they are discussed as ► *reserve granules* and/or as systems to regulate cryoprotection and intracellular osmolality.

See *Dypylidium caninum*. The trivial name for this tapeworm of cats, dogs, and humans was given since the excreted terminal proglottids look like seeds or grains.

Culicidae

Family of ► [Diptera](#).

Culicidae in Germany

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

In Germany about 50 species of the mosquito
family Culicidae have been described, which
belong to the genera:

- *Aedes* (4)
- *Coquillettidia* (1)
- *Culex* (7)
- *Culiseta* (7)
- *Ochlerotatus* (22)
- *Uranotaenia* (1)

Some of them (e.g., *Aedes japonicus*, *Aedes
albopictus*, *Anopheles daciae*, *Culiseta
longiareolata*) have been recently introduced.

Curtuteria

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of echinostomatid trematodes, closely related to *Acanthoparyphium*. *C. australis* is found in Australia and New Zealand.

Cutaneous Larva Migrans

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Cutaneous larva migrans is caused by ► [hookworms](#) mainly of dogs and cats. The itching dermatitis often takes the form of tracks or “► [creeping eruption](#)” indicating the route of migration of the larvae in the epidermis of the skin. These papular and serpiginous lesions sometimes become vesicular and hemorrhagic and are often secondarily infected with bacteria after scratching. These larvae never mature into adults, to live in the intestine, but will die within 3 months at the latest (Fig. 1).

Therapy

Local application of a 15 % tiabendazole ointment.

Cutaneous Larva Migrans, Fig. 1 Human arm with wandering larvae of ► [Ancylostoma caninum](#)

Main Text

Cutaneous Leishmaniasis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Cutaneous leishmaniasis is a special form of ► [Leishmaniasis, man](#), which appears under different clinical signs along the skin of humans (Fig. 1). The disease is induced by specimens of the protozoan species ► [Leishmania](#) transmitted by ► [sandflies](#).

Cutaneous

Leishmaniasis,

Fig. 1 Shows different clinical aspects of the cutaneous – respectively muco-cutaneous leishmaniasis (**a–e**) and a light micrograph of an infected cell (**f**). (**a, b**) Espundia; (**c**) Chiclero sore; (**d**) Oriental sore; (**e**) Uta sores; (**f**) disrupted macrophage containing numerous *Leishmania* amastigotes. *N* nucleus of host cells

Cuterebra

Genus of the fly family Cuterebridae, the species of which induce ophthalmomyiasis in humans in the Americas.

Cuticle

The acellular filamentous type of ► [body cover](#) excreted by an underlying cellularly organized hypodermis. Found, for example, in ► [Nematodes](#), pentastomids, and in arthropods (► [Ticks](#), ► [Mites](#), ► [Insects](#), ► [Crustaceans](#)) with or without ► [chitin](#) (depending on the group).

Cuticulin

In the cortical layer of large ascarids there is a tanned structural protein which does not exhibit the striations characteristic for collagen, and which is not attacked by collagenase. ► [Nematodes](#)/► [Integument](#).

Cutifilaria wenki

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Filarial nematode parasitizing within intra- and subdermal tissues of roe deer and related species.

Cyanobacteria-Like Bodies

The oocysts of ► [Cyclospora species](#) were at first kept for bacteria when seen in the feces of ► [AIDS](#) patients.

Cyathocephalus

Genus of tapeworms in the intestine of freshwater fish.

Cyathocotyle

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of strigeid trematodes.

Cyathospirura Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Nematodes of the family Syngamidae. For example, *Cyathospirura dasyuridis* parasitizes feral cats in Australia; *Cyathospirura* sp. occurs in the intestine of black bears (*Ursus americanus*) in the USA.

Cyathostoma

Synonymous to ► [Syngamus](#).

Cyathostoma Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

These nematodes parasitize the trachea and/or nasal cavities of farmed and wild birds especially in Central Europe. The infections occur by oral uptake of eggs (containing the infectious larvae 3) and by ingesting free larvae 3 within food or within paratenic hosts (e.g., beetles). In contrast to the related ► *Syngamus* species, males and females do not live in a persistent copulatory status. Treatment is successful by application of benzimidazole derivatives (e.g., flubendazole).

Cyathostomum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This genus belongs to the nematode group of the so-called small strongylids of the subfamily Cyathostominae (e.g., *Cyathostomum catinatum*) in horses and other equids. They reach a length of 4–15 mm (♂) and 5–22 mm (♀). They are very

common reaching prevalence rates of up to 100 %. The exact species determination is difficult. After larvae 3 have reached the cecum or colon, they penetrate into the mucosa or submucosa and molt there within 6–12 days reaching the larva 4 status. There they stay for at least 1–2 months (=histiotrophic phase) before they return into the intestinal lumen, where they reach the adult stage after another molt. The prepatent period takes 1.5–3 months, while the patency may last for up to 2.5 years. An important feature of the Cyathostominae is the ► *hypobios*, a phase inside the intestinal wall, where penetrated larvae stop further development for a while. Clinical signs are diarrhea, loss of weight, edema, and shaggy fur. Treatment, e.g., includes ivermectin, doramectin, and moxidectin (0.4 mg/kg body weight twice per year as prevention).

Cyathostomum bronchialis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This nematode species (syn. *Hovorkonema variegatum*, *Cyathostoma variegatum*) reaches as females a length of up to 4.5 cm and as males 4–14 mm. It parasitizes in the trachea and bronchioles of geese, chicken, and many other wild birds. The eggs have a size of 65–90 µm × 40–65 µm and possess an operculum.

Cyathostomum Species

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Cyathostomum catinatum and *C. pateratum* (Subfamily Cyathostominae) belong to the so-called small strongylid nematodes of equids. The female length ranges between 7–29 mm and the male length reaches 6–20 mm. They can be killed with a 2 % ivermectin formulation given to horses.

Cyclophyllida

From Greek: *kyklos* = cercle, *phyllon* = leaf. Order of tapeworms, e.g., ► *Taenia* spp.

Cyclospora cayetanensis

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name

Greek: *kyclos* = spherical, round; *sporos* = spore, capsule, semen; *cayetanensis* = Caribbean origin.

Geographic Distribution/Epidemiology

Worldwide (in warmer countries) several 100,000 persons are infected. Probably all had been infected abroad from their homes during holidays. The species name was given since the first description was done based on material of a patient who came from a Caribbean island.

Morphology/Life Cycle

Starting from 1985 spherical cystic stages of 8–10 µm in diameter had been observed in increasing numbers in the feces of immunocompromised and immunocompetent persons. These

Cyclospora cayetanensis,

Fig. 1 Diagrammatic representations of an unsporulated and a sporulated oocyst of *Cyclospora cayetanensis*. The unsporulated form had originally been described as cyanobacteria-like body (CLB)

**Cyclospora cayetanensis,**

Fig. 2 Light micrograph of an sporulated oocyst of *C. cayetanensis*

stages were at first kept for cyanobacteria and thus described as CLB bodies (= cyanobacteria-like bodies). Other investigators identified these small globules as peculiar stages of the genus ► *Cryptosporidium*, because similar ones were discovered at the same time in large numbers in the feces of AIDS patients. Intense experiments to sporulate these stages (Lit. see (Ortega et al. 1998)) showed later that these parasites are typical coccidians (► *Sporozoa*, Apicomplexa, ► *Alveolata*). The CLB bodies thus represent nothing else than the oocysts of a coccidian species, which is now called *Cyclospora cayetanensis*. Related species have been

described in the intestines of insectivores, rodents, reptiles, and millipedes, too (e.g., *C. caryolytica* in moles and *C. viperae* in snakes). When excreted in the feces the oocysts of *C. cayetanensis* sporulate outside of the human body within 5–13 days at 25–32 °C, thus forming inside of the oocysts wall two ovoid sporocysts with two banded sporozoites which reach a size of $9 \times 1.5 \mu\text{m}$ (Fig. 1). Similar oocysts have also been found in feces of chimpanzees and other monkeys; however, it is still today unclear whether they are related to those found in human feces. In any way they were described as *C. cercopithecii*, *C. colobi*, and *C. papionis*.

Symptoms of Disease

Immunocompromised and immunocompetent persons show identical symptoms of disease, since both groups suffer for 2–9 weeks from diarrheas that appear watery and are produced three to four times per day. These diarrheas may disappear also without treatment, but affected persons are hit by weakness and abdominal pain.

Diagnosis

Microscopic investigation of native fluid feces or concentration methods (► [S.A.F.C.](#), ► [M.I.F.C.](#)) show the typical oocysts. The ► [Ziehl-Neelsen](#) stain also can be used to show the oocyst walls (Figs. 1 and 2).

Infection

Oral uptake of sporulated oocysts within fecally contaminated food or within drinking water.

Prophylaxis

Avoid potentially contaminated food or drinking water.

Incubation Period

Two to seven days.

Prepatent Period

About 1 week.

Patency

Immunocompetent persons: 2 weeks; immunocompromised persons: up to 7–12 weeks.

Therapy

Not necessary in persons with light symptoms. In cases of severe diarrheas cotrimoxazole (2 × 800 mg sulfamethoxazole/160 mg trimethoprim daily for a week) showed clearance of symptoms. Diarrheas of children were stopped within 4 days by application of 5 or 25 mg cotrimoxazole per kg body weight for 3 days.

Cyclospora Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Classification

Genus of ► [Coccidia](#).

Important Species

Table 1.

Life Cycle

In diarrheic stools of some immunocompetent, but mostly of immunodeficient people spherical, 8–10 µm-sized cysts were described as CLB = ► [cyanobacteria-like bodies](#), which

Cyclospora Species, Table 1 Important species of the genus *Cyclospora*

Species	Host	Infected tissues	Oocyst size	Prepatent period
<i>Cyclospora cayetanensis</i>	Humans (AIDS patients)	Intestinal cells	8–10 μm	?
<i>Cyclospora caryolytica</i>	Mole (<i>Talpa</i>)	Intestinal cells	8–12 μm	?
<i>Cyclospora viperae</i>	Snakes	Intestinal cells	9–12 μm	?

Cyclospora Species, Fig. 1 Diagrammatic representation of an unsporulated and a sporulated oocyst

turned to be typical coccidian oocysts belonging to the genus *Cyclospora*, which is known from millipedes, insectivores, rodents, and reptiles. The human species is now called *C. cayetanensis*. Outside the body within 5–13 days (at 25–32 °C), 2 sporocysts are formed within each ► **oocyst**. These sporocysts contained each 2 sporozoites with a size of 9 × 1.5 μm. Infection of humans apparently occurs via inoculation of such oocysts (Fig. 1). However, the further development is still unknown.

Disease

► **Cyclosporiasis**, ► **ciprofloxacin**, ► *Cyclospora cayetanensis*.

Cyclosporiasis

In diarrhoeic stools of man especially in AIDS-patients the 8–10 μm-sized, unsporulated oocysts of ► *Cyclospora cayetanensis* have been described. At first they were misdiagnosed as CLB (► **Cyanobacteria-Like Bodies**). They

apparently induce watery intermittent ► **diarrhoea** (3–4 times per day), which last for 2–9 weeks and may disappear without treatment. Infection apparently occurs by inoculation (with contaminated food) of sporulated oocysts containing 2 sporocysts with 2 sporozoites. The source of the oocysts is not yet clear, since *Cyclospora* exists in many animals without clinical symptoms. **Treatment** may be carried out with Cotrimoxazol (2 × 800 mg Sulfamethoxazol/160 mg Trimethoprim).

Cyfluthrin

Ectoparasiticide (► **Arthropodicidal Drugs**) of the group of pyrethroid acting against flies on grazing cattle.

Cyst Wall

Many parasitic ► [Protozoa](#) (e.g., *Giardia*, ► [Entamoeba histolytica](#), ► [Coccidia](#)) are capable of undergoing ► [encystation](#), which involves formation of a cyst wall either outside or inside the ► [cell membrane](#). This cyst wall may be single- or multilayered. Walls formed outside the ► [plasmalemma](#) are produced by ► [exocytosis](#) of materials (► [Wall-Forming Bodies](#)). Cyst walls have two main tasks: (1) to protect the organism against unfavorable ► [environmental conditions](#) when passing from one host to another, and (2) to create spaces for reorganization and ► [nuclear division](#). Cyst walls may also aid the parasite in its transmission from one host to another by facilitating attachment to host cell surfaces.

The cyst wall has one layer in cysts of ► [Entamoeba histolytica](#), *Giardia*, and some ciliates, such as the fish parasite ► [Ichthyophthirius multifiliis](#) and the human parasite ► [Balantidium coli](#). There are usually two types of cysts in the stages of ► [coccidia](#) in feces: the oocysts and the sporocysts. The ► [oocyst](#) wall is usually two-layered but in a few species it may have four layers. It is formed by two types of cyst- ► [wall-forming bodies](#) (► [Eimeria](#)) (Fig. 1).

The chemical composition of cyst walls varies according to the species, although proteins are

(a) Suture of the sporocyst wall (characteristic of the genera *Sarcocystis*, *Toxoplasma*, *Isospora*); the wall ruptures here during the excystation of the sporozoites inside the intestinal tract of the host ($\times 40,000$). (b) *Isospora* sp. from sparrows. Section through a sporocyst with two (of four) sporozoites (S) in the section plane. Note the large, membrane-bound residual body ($\times 12,000$). (c, d) *Sarcocystis* sp. oocysts

(OC) contain two sporocysts with four sporozoites when excreted with feces; due to the smooth oocyst wall mostly sporocysts (d) are found in feces ($\times 2,000$). A amylopectin, IN inner part of the sporocyst wall, L lipid, MI mitochondrion, MN micronemes, N nucleus, O outer part of the sporocyst wall, PE pellicle, RB residual body, RE retractile body, RH rhoptries, S sporozoite, SU suture, SW sporocyst wall

usually the basic component. The cyst walls of *E. histolytica* and *G. lamblia* contain proteins which are keratin-like or elastin-like albuminoids, composed of lysine, histidine, arginine, tyrosine, glutamic acid, and glycine.

The two-layered oocyst wall of the sporozoans is periodic acid-Schiff-positive (PAS-positive).

The outer layer of these oocysts consists mainly of fatty alcohols (e.g., hexacosanol), some phospholipids, and fatty acids. It contains no carbohydrates or proteins. The inner layer is composed of glycoproteins and contains most of the carbohydrates found in the oocyst wall. These carbohydrates are composed of mannose, galactose,

Cyst Wall, Fig. 3 (a–d) Myxo- (a) and microsporidian cysts (b, d) in electron (a, c) and light micrographs (d). (a) *Myxosoma* sp. from fish skin, due to the oblique section only one polar capsule is seen ($\times 10,000$). (b, d) *Glugea* sp. from intestinal wall of fish (b $\times 3,500$, d $\times 2,000$). (c)

Nosema sp. from tissues of *Pimpla* sp. ($\times 12,000$). DL densification in EN, EN light endospore, ETU enlarged TU, EX dense exospore, HC host cell, HT host tissue, N nucleus, RL ribosomes, S spores, SC sporoplasm, SU suture of valves TU polar tube (filament), VA valve of shell

glucose, and hexosamine. The oocyst wall is highly resistant to the passage of potassium dichromate, sodium hypochloride, sulphuric acid, and sodium hydroxide and therefore these chemicals are used in the storage and cleaning of oocysts. It is permeable to O_2 , CO_2 , NH_3 , methylbromide, carbon disulphide, and various organic solvents. The oocyst wall is highly susceptible to mechanical pressure and therefore may be easily ruptured by shearing forces. Thus, the mechanical rupture of oocysts in the gizzard of the avian host is likely to be the normal method of excystation of avian coccidia. The ► **micropyle** (a pre-formed opening) is probably rarely used as a passage for the escape of sporocysts. The sporocysts in the oocyst are bound by a two-layered wall, the inner layer of which is relatively smooth (Fig. 2). The sporocysts of eimerians have an opening which serves as an

exit for the sporozoites. This is closed by the ► **Stieda body**, which can be dissolved by trypsin. The sporocysts of ► *Isospora* and the tissue-cyst-forming coccidia (e.g., ► *Sarcocystis*, *Toxoplasma*) have sutures on which the excystation fluids act, causing collapse of the ► **sporocyst wall** (Fig. 2).

The cyst walls of the members of the ► **Myxozoa** and ► **Microspora** are at least double-walled in most species (Fig. 3), but the layers can only be resolved by electron microscopy. In Myxozoa, the wall consists of two valves that open at pre-formed sites to release the infectious sporoplasm (Fig. 3a). The Microspora have developed a hollow tube that protrudes from the surface of the wall (Figs. 3b and 4). It penetrates into a host cell and the infectious sporoplasm is passed through it. The ► **exospore** layer in Microspora is proteinaceous and is 15–100 nm

Cyst Wall, Fig. 4 Cyst stages (a, c, f–i light micrographs, b, d, e electron micrographs). (a, b) Microsporidian spore (*Nosema*). (a) $\times 2,500$, (b) $\times 15,000$. thick, depending on the species. The endospore layer is chitinous and ~150–200 nm thick (Fig. 4). The ► **Spores** are Gram-positive (i.e., stain reddish purple with the Gram stain), a fact that is of diagnostic value. They are also stained light blue by Giemsa. Besides these typical cysts, some genera such as *Toxoplasma* and *Sarcocystis*, form so-called ► **tissue-cysts**. They develop from a “normal ► **parasitophorous vacuole**,” the membrane of which becomes fortified to a so-called ► **primary cyst wall**, which starts to form species-specific protrusions. Such tissue-cysts, while inside divisions go on, may become covered by host defense cells so that a ► **secondary cyst wall** is produced (e.g., *Sarcocystis ovifelis*, ► **Tissue Cyst**).

Encystation is also done by ► **cercariae** of some digenean ► **trematodes** (► *Digenea*) which excrete (via cystogenous glands) material to produce the wall of metacercariae, *Fasciola*. Further similar processes are seen in Acanthocephala/Cystacanth.

Cystacanth

An infective ► **acanthella** is commonly called a cystacanth, referring to the cyst-shaped larvae of *Macracanthorhynchus hirudinaceus* (► **Acanthocephala**, Fig. 2) or ► *Moniliformis moniliformis* (► **Acanthella**, Fig. 2C). Most acanthocephalans, however, have elongated sausage-shaped infective larvae (► **Acanthella**, Fig. 2C), which resemble immature adults with an invaginated ► **praesoma**. Such larvae have well-developed sexual organs whereas the “cystacanth-like larvae,” with a large gap between them and the surrounding envelope, are usually retarded in the development of their sexual organs and may have a very solid body wall (► **Acanthella**, Fig. 2C). Therefore the general term infective larva appears more appropriate than the misleading term cystacanth. But usually names that have become established cannot be changed anymore.

Cystacanths have almost-closed tegumental pores and compressed crypts in their outer membranes, corresponding to the dormant metabolism of this larva. The size of the ► **surface coat** usually significantly exceeds that of the adult worms inside the gut of the final host.

Cystatin

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This compound, which is excreted by nematodes, acts as a powerful immune modulatory substance offering a long undisturbed life of the nematodes in their hosts.

Cystic echinococcosis

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Disease due to fluid filled cyst stages in intermediate hosts of ► *Echinococcus granulosus*.

Cysticeroid

Tailed second larva, e.g., of ► **tapeworms** of the families Anoplocephala, Davaneidae, Dipylidae, and Hymenolepididae (► **Cestodes**, Eucestodes).

Cysticercosis

Pathology

Cysticercosis results from the development of larval ► [tapeworms](#) in humans harboring adult ► *Taenia solium* (► [Autoinfection](#)) or from ingesting soil containing eggs shed in the feces of humans, in areas where there are no latrines, or where they are so filthy that they are not used. Humans are accidental intermediate hosts and pigs are the normal intermediate hosts; their meat being “measly pork”. Oncospheres released from eggs penetrate the intestinal mucosa and develop into bladder-like, ► [cysticercus](#) larvae of 1–2 cm which develop in many tissues, mostly in skeletal muscle and subcutaneous tissue. Clinically they are most serious when located in the central nervous system or in the eye where they persist for months to years. The intact cysticerci are surrounded by a fibrous capsule and rarely give rise to symptoms, unless they involve special areas of the brain such as the aqueduct or are present in large numbers. However, degenerating cysticerci give rise to fever with an intense eosinophilic inflammatory reaction (► [Eosinophilic Reaction](#)) accompanied by tissue swelling, being especially serious in the brain. The dead parasites often calcify and become demonstrable by radiography; the living cysticerci can be diagnosed by computerized axial tomography and magnetic resonance imaging and should correlate with positive serological findings.

Main Clinical Symptoms

Dysfunction of the organs, within which the cysticerci are located.

Incubation Period

8–10 weeks.

Prepatent Period

Patent Period

2 years.

Diagnosis

Serodiagnostic methods, computer tomography, ► [Serology](#).

Prophylaxis

Avoid contact with human feces.

Therapy

Treatment with praziquantel, see ► [Cestodocidal Drugs](#).

Immune Responses

The cysts have developed mechanisms to avoid the host inflammatory and immune response. The analysis of experimental infections of rodents with *Taenia crassiceps* or *T. taeniaeformis* has significantly contributed to our understanding of the host-parasite relationship.

Complement and Macrophages Granulocytes

Destruction of oncospheres in sera of patients or immune animals is mediated by the classical complement pathway. However, also the primary resistance to *T. taeniaeformis* infection in naive mice is complement-dependent. C3b is deposited on the surface of oncospheres and proto-oncosphere larvae but only in resistant and not in susceptible murine hosts is C5a produced. In contrast, complement has little effect on viable metacestodes.

In experimental infections, the developing ► [metacestode](#) is surrounded by neutrophils and eosinophils, which appear to have no detrimental effect on the parasite. The formation of infiltrates may be directly initiated by the parasite via the production of several chemotactic factors. *Taenia*-induced macrophages upregulate molecules like death ligand 1 (PD-L1) and PD-L2. These molecules are responsible for the inhibition of parasite-specific response of lymphocytes, thus

representing an immune-escape mechanism operative during *Taenia* infection.

B Cells and Antibodies

Antibodies are thought to play a decisive role in the immune response to ► *Taenia* oncospheres. Passive immunization studies have shown that protection can be transferred with antibody alone, while T cells are involved in the generation of protective immunity. In contrast, antibodies have little effect on metacestodes. However, most viable parasites contain immunoglobulin on their surface, of which the majority is not specific for the parasite. It has been suggested that the parasites may have Fc receptors for host immunoglobulins, which could be taken up, digested, and thus serve as a primary protein source for the parasite.

T Cells

Acute infections with taeniid oncospheres as well as viable cysts are associated with suppression of the host immune response. For example, spleen cells from acutely infected rats displayed decreased mitogenic responses, and in infected pigs a decreased number of CD4⁺ T cells in the peripheral blood has been reported. The immune-suppressive effects seem to be mediated, at least in part, by modulation of the role of macrophages as antigen-presenting cells and appear to be dependent on the presence of viable parasites.

In mice infected with *Taenia crassiceps*, elevated levels of IgG1 and IgE suggested a dominant Th2 response. Increased production of IL-4, IL-6, and IL-10 has been detected, and active infection was also associated with a suppression of pro-inflammatory and Th1 cytokines.

The death of the parasite is associated not only with a granulomatous response but also with a switch to IgG2a production, a pattern associated with IFN- γ production. In humans, parasite death is accompanied by elevations of neopterin within the spinal fluid, a marker for macrophage activation. In addition IL-12 and IFN- γ expression has been detected in granulomas surrounding dying cyst, consistent with the idea, that death of the metacestodes results in a shift to a Th1 response.

Evasion Mechanisms

Molecules able to detoxify reactive oxygen intermediates, such as superoxide dismutase and glutathion-S-transferase, were purified from *T. taeniaeformis*. ► *Paramyosin*, excreted by ► *T. solium*, is able to bind to C1 thereby inhibiting the classical complement activation. The protease inhibitor taeniaestatin, a glycoprotein secreted by *T. taeniaeformis* metacestodes, not only inhibited the classical and alternative pathway of complement activation but also suppressed mitogen- or IL-1-induced proliferation of rat spleen or mouse thymus cells, respectively. Furthermore, taeniaestatin interfered with neutrophil chemotaxis and aggregation in vitro. Prostaglandin E2 isolated from the excretory fluid of *Taenia* metacestodes may contribute to the inhibition of Th1 responses.

Cysticercus

Name

Greek: *kystis* = bladder, *kerkos* = tail.

Type of the second tapeworm larva (► *Eucestoda*, ► *Taenia solium*), bladder worm, ► *Cysticercosis*, Figs. 1 and 2.

Cysticercus, Fig. 2 Evaginated *Cysticercus* in human eye

Cysticercus cellulosae

Larval stage of ► *Taenia solium* in pigs, ► *Nervous System Diseases, Swine*, ► *Cysticercus*, Figs. 1 and 2.

Cysticercus in Humans

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *kystos* = cyst; *kerkos* = tail; Latin: *cellula* = small cell; *racemosus* = grape-like.

Geographic Distribution/Epidemiology

Especially common in Latin America and in countries with pig farms (e.g., China, Africa, India); in

some countries these cysticercus are diagnosed in 2–3 % of all autopsies. In Europe only rare cases occur, in those countries with intense meat inspection (e.g., Germany).

Morphology/Life Cycle

The so-called *Cysticercus cellulosae* represents the larval stage of the tapeworm ► *Taenia solium*, which parasitizes inside the intestine of humans. Normally the *Cysticercus cellulosae* occurs in tissues of the intermediate host pig (wild and farmed ones). If humans ingest eggs of this tapeworm, they may become intermediate (paratenic) hosts, too. Since the larva (oncosphaera) is able to hatch inside the human intestine, it enters via bloodstream many organs, where the cysticercus is finally formed. The cysticercus grows up to a fluid-filled, translucent bladder of about 1.5–2 cm in diameter. Inside of this bladder the scolex of the later adult tapeworm is formed from several undifferentiated embryonic cells. The scolex is already equipped by the typical 4 suckers and the rostrum with its crown of specific hooks (Fig. 1). In humans such bladders are a dead end with respect to the life cycle. However, from pigs it can be transmitted to the final host: man. In some rare cases the bladder produces protrusions thus inducing the aspect that was described by ► *Virchow* as *Cysticercus racemosae* (which refers to the grape-like arrangement of the protoscolices).

Symptoms of Disease (Cysticerciasis)

Depending on the infected human organ the symptoms of disease may differ considerably reaching from subclinical until fatal. In cases of cysticerci inside muscles muscle pain and paresis were recorded. In cases of brain infections motoric and sensoric malfunctions may occur as well as severe psychological/psychic defects. Cysticerci inside the spinal cord may introduce complete paresis, and cysticerci inside eyes may lead to loss of sight (Fig. 2).

Cysticercus in Humans,

Fig. 1 Light micrograph of a *Cysticercus cellulosae* bladder containing the spherical embryonic center

Cysticercus in Humans, Fig. 2 Macrophoto of a cysticercus in a human eye

Cysticercus in Humans, Fig. 3 Human brain showing cysticerci (arrows) by help of computer tomography

Diagnosis

In cases of potential neurocysticercosis computer tomography or MRT will show such cysticerci (Fig. 3). In cases of cysticercosis in other organs serological test (e.g., ELISA, Western blot, etc.) will give information; however, false negative results may be obtained in a range between 10 % and 30 %.

Infection

Oral uptake of *T. solium* eggs within food contaminated with remnants of human feces. Furthermore ► [autoinfection](#) is possible, if terminal proglottids are in human intestine thus setting free the infectious eggs being followed by hatch of the larva.

Prophylaxis

Avoidance of contacts to human feces, especially on wild camping sites and on highway parking sites without toilets. Keep human food free from flies, and take care to wash salad in rural regions.

Incubation Period

Eight to ten weeks.

Prepatent Period

About 8 weeks p.i. the cysticercus has reached a diagnosable size.

Patency

At least 2 years.

Therapy

Albendazole (15 mg/kg body weight daily for 8 days) is one of the drugs of choice as well as praziquantel (50 mg/kg body weight for 15 days). Since in cases of a neurocysticercosis the symptoms may become increased, it is strongly recommended to ingest in addition to the anthelmintics corticosteroids and anticonvulsion acting compounds. In the rare cases of the formation of a hydrocephalus internus and larger ventricular cysts neurosurgery is inevitable (See ► *Taenia solium*).

Cystoisospora

David S. Lindsay
Department of Biomedical Sciences and
Pathobiology, VA-MD College of Veterinary
Medicine, Blacksburg, VA, USA

Synonyms

Isospora

General Information and Life Cycle

Classification

Genus *Cystoisospora* was proposed as a new member of the phylum Apicomplexa, class Coccidia, order Eimeriida, and family Sarcocystidae in 1977 by Dr. J. K. Frenkel to contain the mammalian coccidia in the genus *Isospora* that had recently been found in 1972 to make monozoic tissue cysts (cysts that contain a single asexual infective stage called a zoite) in the tissues of experimentally infected rodents (paratenic hosts). The sporulated oocysts of this genus contain two sporocysts that do not contain a Stieda body, and each sporocyst encloses four sporozoites consistent with other heteroxenous tissue cyst-forming coccidia *Toxoplasma*, *Hammondia*, *Neospora*, *Besnoitia*, *Frenkelia*, and *Sarcocystis* present in this family. The type species is *C. felis*.

Important Species

Coccidial parasites in the genus *Cystoisospora* (Table 1) are important agents of intestinal disease in humans (*C. belli*), neonatal pigs (*C. suis*), young cats (*C. felis*, *C. rivolta*), and young dogs (*C. canis*, *C. ohioensis*, *C. burrowsi*). These coccidia are host specific for the definitive host (host that produces oocysts). Some of these species infecting cats and dogs have evolved to use a paratenic (transport host) in their life cycle

Cystoisospora, Table 1 Important species of the genus *Cystoisospora*

Species	Host/location	Oocyst range in μm	Prepatent period	Paratenic host
<i>Cystoisospora felis</i>	Cats/small intestine	38–51 × 27–39	7–11 days	Yes
<i>C. rivolta</i>	Cats/small intestine	18–28 × 16–23	4–7 days	Yes
<i>C. canis</i>	Dogs/small intestine, cecum	34–40 × 28–32	8–10 days	Yes
<i>C. ohioensis</i>	Dogs/small intestine, cecum, colon	19–27 × 18–23	5–6 days	Yes
<i>C. burrowsi</i>	Dogs/small intestine, cecum, colon	17–22 × 16–19	6–9 days	Yes
<i>C. suis</i>	Pigs/small intestine, cecum, colon	20–23 × 17–19	4–5 days	No
<i>C. belli</i>	Humans/small intestine, cecum, colon, bile ducts	20–36 × 10–19	9–17 days	No

Cystoisospora, Fig. 1 Life cycle of *Cystoisospora canis*

Cystoisospora, Fig. 2 Asexual and sexual stages and unsporulated oocysts of *Cystoisospora canis*. (a) Last-generation schizonts with merozoites (arrows), H&E

stain. (b) Late macrogamonts/oocysts (O), H&E stain. (c) Unsporulated oocysts in a fecal flotation. Two sporoblasts are present in one unsporulated oocyst (arrow)

reflecting their carnivorous way of life. Intestinal coccidiosis caused by *C. suis* in nursing pigs is a serious production problem worldwide. *Cystoisospora belli* is a cause of diarrhea in immunocompetent and immunocompromised patients. The infection in AIDS patients can be chronic and prone to reoccurrence once anticoccidial treatment has been stopped.

Cystoisospora Life Cycle

The life cycle of *Cystoisospora* species infecting cats and dogs can be divided into the developmental cycle in the definitive host following ingestion of sporulated oocysts or monozoic tissue cysts from infected paratenic hosts. The developmental cycle in the paratenic host following ingestion of sporulated oocysts is a separate occurrence (Fig. 1).

Development in the Definitive Host Following Ingestion of Sporulated Oocysts

Sporulated oocysts (Table 1) are orally infective for the definitive host undergoing asexual multiplication by schizogony (2–4 generations) in enterocytes or intestinal cells in the lamina propria followed by gametogenesis and the production of unsporulated oocysts. Sporozoites exit the oocyst via deviations in the oocyst wall after they have become motile, and the sporocyst wall has collapsed along four platelike junctions. Sporozoites invade intestinal cells and the first asexual division is by endodyogeny. Additional asexual stages divide by schizogony and produce additional merozoites. The last generation of merozoites becomes sexual stages which are either male stages called microgamonts that contain many sperm-like microgametes or female stages

Cystoisospora, Fig. 3 Monozytic tissue cyst of *Cystoisospora felis* in the lymph node of a mouse. The zoite (N) is in a thick-walled (arrow) tissue cyst. H&E stain, bar = 10 μ m

containing a single nucleus called macrogamonts (Fig. 2). Microgametes fertilize macrogamonts and an oocyst wall is produced enclosing the zygote. Unsporulated oocysts are excreted with the feces. Additionally, some sporozoites or merozoites leave the intestine and produce extraintestinal stages consisting of 2–15 organisms in mesenteric lymph nodes, spleen, and other tissues. Presently, it is not known if these stages represent a true tissue cyst stage or they are just asexual stages that have wandered from the intestinal tract and found receptive cells in these tissues. These extraintestinal stages in the definitive host are not the same as the monozytic tissue cysts that are produced in paratenic hosts (see below).

The prepatent periods of important *Cystoisospora* species are given in Table 1. Oocysts are excreted unsporulated or beginning to sporulate with two sporoblasts (Fig. 2c). Oocysts sporulate rapidly in warm, moist environments and can become infective within 24 h. The size and host of origin are most important in identifying *Cystoisospora* oocysts.

Development in the Definitive Host Following Ingestion of Paratenic Hosts

The endogenous developmental cycle in the definitive host is the same as that that occurs after the

ingestion of sporulated oocysts. The numbers of asexual cycles are the same, but the prepatent period may be decreased by a day. This finding suggests that monozytic tissue cysts contain stages equivalent to sporozoites.

Development in the Paratenic Host After Ingestion of Sporulated Oocysts

Monozytic tissue cysts may be present in many tissues of a paratenic (transport) host, but typically most can be found in the mesenteric lymph nodes (Fig. 3). A monozytic tissue cyst wall develops below the parasitophorous vacuole membrane, and the host cell nucleus is outside of monozytic tissue cyst wall. Monozytic tissue cysts are orally infectious for definitive host but not paratenic host. A monozytic tissue cyst contains a single organism called a zoite that resembles a *Cystoisospora* sporozoite which has a single nucleus, one or occasionally two crystalloid bodies, amylopectin granules, micronemes, dense bodies, rhoptries, and a conoid. Monozytic tissue cysts of *C. rivolta* can survive and be infectious for up to 23 months (Dubey 1979) and probably the life of the paratenic host.

Bioassay studies using tissues from naturally and experimentally infected animals have demonstrated a wide host range for paratenic hosts of *Cystoisospora* species infecting cats and dogs. Gerbils, guinea pigs, rabbits, swine, cattle, sheep, camels, and chickens have been shown to contain orally infectious stages in their tissues capable of inducing oocyst production in appropriate definitive hosts.

Cystoisospora belli Monozytic Tissue Cysts in AIDS Patients

Monozytic tissue cysts of *C. belli* can be found in mesenteric (Fig. 4) and other lymph nodes of patients with AIDS. These tissue cyst stages are similar in structure to the monozytic tissue cyst stages present in the tissues of paratenic hosts fed feline and canine *Cystoisospora* species. Recurrent clinical disease is common in both immunocompetent and AIDS patients infected with *C. belli*. It is possible that reactivation of the zoites present in the monozytic tissue cysts occurs and that these stages migrate to the

Cystoisospora, Fig. 4 Monozytic tissue cyst (arrow) of *Cystoisospora belli* in the mesenteric lymph node of an AIDS patient. H&E stain

human intestinal tract and produce patent infections (Lindsay et al. 2011). It is common for AIDS patients to relapse with clinical disease once *C. belli* treatment has been stopped suggesting reactivation of these stages after treatment is stopped.

Clinical Relevance

The clinically important *Cystoisospora* species of companion animals, domestic animals (neonatal pigs), and humans are listed in Table 1. Infection with these parasites in companion animals and neonatal pigs has a worldwide distribution, while *C. belli* in humans is primarily found in tropical, subtropical, and warm temperate regions (Lindsay et al. 2011).

Cats and Dogs

Cystoisospora species can cause diarrhea in puppies and kittens that serve as the definitive host (Dubey et al. 2009). Diarrhea caused by *Cystoisospora* species is seen in puppies and kittens soon after they are weaned or subjected to environmental stress such as transportation and being placed in a new environment. Diarrhea in these animals is usually free of blood.

Cystoisospora, Fig. 5 Necrotic enteritis caused by *Cystoisospora suis*. The villi are blunted and necrotic cells are in the lumen. Developmental stages (arrows) are present in some of the epithelial cells

Dehydration can occur in heavily infected animals. Animals usually recover and obtain normal body weights in a few weeks.

Neonatal Pigs

Cystoisospora species do not use cattle, sheep, goats, horses, rabbits, or chickens as definitive hosts. Coccidia in the genus *Eimeria* occur in these animals and they often are clinically important. Neonatal coccidiosis caused by *C. suis* is an important production problem in modern swine-producing facilities worldwide (Fig. 5). Signs of disease occur in formerly healthy nursing pigs between 7 and 11 days of age. Yellowish to grayish diarrhea is the major clinical sign. The feces are initially loose or pasty but can become more fluid as the infection progresses. Piglets usually continue to nurse, develop a rough hair coat, become dehydrated, and have depressed weight gains. Litters within the farrowing house vary in the degree to which they demonstrate clinical

signs, and not all piglets within a litter are equally affected. Morbidity is usually high, but mortalities are usually moderate. Concurrent bacterial, viral, or other parasitic infections may lead to extreme mortalities and complicate diagnosis.

Nonhuman Primates

Little has been done with the coccidia of nonhuman primates, and we know little about the prevalence or general biology of these parasites. *Cystoisospora arctopitheci* has been reported to have a wide host range that includes six genera of New World nonhuman primates, four families of carnivores, and one marsupial species (Lindsay 1990). It develops in enterocytes in the small intestine and has a prepatent period of 7 days. No extraintestinal stages have been documented. It can be pathogenic under experimental conditions for marmosets (*Saguinus Geoffroyi*). Oocysts of *C. callimico* and *C. endocallimici* have been described from Goeldi's marmoset (*Callimico goeldii*) and those of *C. scorzai* from a uakari monkey (*Cacajao rubicundus*).

Humans

Cystoisospora belli infection occurs in tropical, subtropical, and warm temperate regions (Lindsay et al. 2011). Infections in temperate areas usually have a history of foreign travel to an endemic area or homosexual activity. Transmission is via ingestion of sporulated oocysts in contaminated drinking water or by ingestion of produce contaminated with *C. belli* oocysts. Improving sanitation and water quality in endemic areas will decrease transmission of *C. belli*.

Symptoms of *C. belli* infection include diarrhea, steatorrhea, headache, fever, malaise, abdominal pain, vomiting, dehydration, and weight loss. Stool samples usually do not contain blood. The symptoms are often chronic with oocysts present in the stool or developmental stages present in intestinal biopsies for several months to years. Recurrences are common and can occur as long as 10 years after successful treatment. Symptoms and resulting disease are more severe in infants and young children. Clinical disease caused by *C. belli* infection is usually more severe in immunocompromised patients than in immunocompetent patients.

Cystoisospora belli infection produces diarrhea in AIDS patients that is often very fluid and secretory-like and leads to dehydration requiring hospitalization. Fever and weight loss are also common findings. Relapse of clinical infection frequently occurs once specific anti-*C. belli* treatment has been stopped in AIDS patients. Occasional infections with *C. belli* in the gallbladder epithelium have been reported, but clinical signs in these cases are not consistent with coccidiosis, and diagnosis is made after biopsy for other suspected causes (Lindsay et al. 2011).

Cystoisospora Species of Carnivores

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *kystis* = cyst; *isos* = identical; *sporos* = spore, seed. Latin: *felis* = cat;

Cystoisospora Species of Carnivores, Table 1 *Cystoisospora* species

Species	Final hosts/tissues	Paratenic hosts	Oocyst (size μm)	Prepatent period (days)	Pathogenicity
<i>C. canis</i>	Dogs (small intestine, lamina propria)	Rodents, pigs, hamster	36–44 $\times$ 29–36	8–11	++
<i>C. ohioensis</i>	Dogs (whole intestine, epithelial cells)	Pigs, water buffaloes, donkey, cats, dogs	19–27 $\times$ 18–23	6	+
<i>C. burrowsi</i>	Dogs (enterocytes, lamina propria)	Mice, rats, cattle	16–23 $\times$ 15–22	6–9	+
<i>C. felis</i>	Cats (enterocytes, small intestine)	Rodents, ruminants, hamster, cats, rabbits	30–53 $\times$ 23–37	6–7	+
<i>C. rivolta</i>	Cats (whole intestine)	Rodents, ruminants, hamster, cats, rabbits	22–30 $\times$ 21–27	5–7	+

++ medium until high pathogenicity
+ medium pathogenicity

canis = dog; *ohioensis* = from Ohio, USA state; Burrows, Rivolta: names of scientists.

Geographic Distributions/Epidemiology

Worldwide in carnivores (dogs, cats, and their wild relatives) (Table 1); especially young animals as well as immunosuppressed individuals are severely affected, while adult animals show mostly only low-graded symptoms of an infection. In Europe infection rates of cats and dogs range between 1 % and 5 %. In humans ► *Isospora belli* is described, which should also be listed as a *Cystoisospora* species.

Morphology/Life Cycle

The life cycle of these species occurs in canids or felids as final hosts; however, in all cases a broad spectrum of paratenic hosts may become additionally infected (Table 1; Fig. 1). In the final host the typical coccidian life cycle (schizogony, gamogony, sporogony) takes place inside a parasitophorous vacuole (► *Isospora*, *Eimeria*),

which ends by the fecal excretion of typical unsporulated oocysts (Fig. 2), which sporulated outside the body within a few days giving rise to two sporocysts with four sporozoites (Fig. 3). These stages are infectious for cats and dogs, where schizogony is initiated. In case that paratenic (intermediate) hosts ingest such sporulated oocysts, the hatching sporozoites enter various types of tissue cells, wherein they remain without starting any further development (Fig. 1). They can easily be recognized since these sporozoites contain a large “residual body” consisting of reserve material, which is only used up, if schizogony starts in a final host, who had fed meat containing such stages (Fig. 1). These “dormant” sporozoites remain infectious for at least 2 years and thus consequently have been termed by Miles Markus (University of Witwatersand, South Africa) as **hypnozoites**. Another name for these stages is **dormozoites**. Thus this life cycle is a so-called heteroxenous pathway of transmission, while the typical ► *Isospora* species reproduce in a monoxenous life cycle. This was the reason why Jack Frenkel (USA) proposed to separate the heteroxenous species as *Cystoisospora* thus dividing them from typical *Isospora* species, which do not form tissue

Cystoisospora Species of Carnivores, Fig. 1 Life cycle of *Cystoisospora felis*. The three phases of the typical coccidian life cycle pass in the epithelial cells of the ileum of the final host (cat). The unsporulated oocysts (1) sporulated outside in the cats feces and thereby form inside two sporocysts, which include each four sporozoites (2). If an oocyst is ingested by a paratenic host (e.g., a mouse, B), the sporozoites leave the sporocysts and penetrate into the

tissues of this host and finally enter a cell, where a parasitophorous vacuole is formed around the sporozoite. Since this stage does not undergo any division, but stays for up to 2 years as a typical sporozoite, they now were called **hypnozoites** (Greek: *hypnos* = sleep) or by another term "**dormozoites**" (3). Both terms mean the same: these stages are waiting unchanged inside the paratenic host until they are ingested by the final host cat

cyst stages in other hosts but perform their whole life cycle inside cells of the intestine of their hosts.

Symptoms of Disease

Infections of adult final hosts introduce mostly only slight symptoms, which start between 3 and 8 days after infection. In case of severe infections (in immunosuppressed animals), however, liquid pasty feces were excreted – often mingled with blood. In extreme cases the destruction of the intestinal wall may introduce phases of hemorrhagic enteritis which may lead to death. Slight infections are self-limiting and stop after 1 week

and mostly introduce immunity. The infections of paratenic hosts mostly do not lead to significant symptoms, since the parasites are included each in a parasitophorous vacuole and thus do not interact with the immune system. Recent findings showed that these cysts may also occur in humans since Houk and Lindsay (2013) reproduced these stages in human tissue cells.

Diagnosis

Determination of the oocyst size and appearance after isolation from feces by help of concentration methods (► [M.I.F.C.](#), ► [S.A.F.C.](#), ► [flotation](#)).

Cystoisospora Species of Carnivores,
Fig. 2 *Cystoisospora felis*: unsporulated oocyst

Cystoisospora Species of Carnivores,
Fig. 3 Sporulated oocyst containing two sporocysts with each four sporozoites

Infection

Oral, by uptake of sporulated oocysts with contaminated food or by ingestion of “dormozoites” in raw or undercooked meat of intermediate hosts.

Incubation Period

The length varies depending on the species: 3–4 days (*C. ohioensis*) or 6–8 days (e.g., *C. canis*).

Prophylaxis

Discharge of any fecal deposits, e.g., followed by hot-steam-cleaning of breeding rooms of dogs and cats. Dogs and cats should not be fed by raw or undercooked meat.

Prepatent Period

The length of the phase until infectious oocysts are produced depends in the mode of infection. It takes mostly 1–2 days less to produce oocysts, when final hosts ingest meat containing

dormozoites compared to the oral uptake of sporulated oocysts (Table 1).

Patency

This patency is species specific and ranges from 4 to 12 days in *C. burrowsi* until 4 weeks in infection with *C. felis* and *C. canis*.

Therapy

The drug of choice for treatment of final hosts is toltrazuril (10 mg/kg bodyweight) oral for 4–5 days. Treatment of paratenic hosts is not necessary.

Cystoopsis acipenseri

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This nematode species lives in pairs in cysts in the skin of sturgeons. The males are small and slender with an eversible spicule. The female's posterior

is enormously swollen into a globular mass containing the intestine and the coils of the single reproductive system.

Cystozoites

Developing stage inside of apicomplexan tissue-cysts (e.g., ► *Toxoplasma gondii*, ► *Sarcocystis* species); another name is ► **bradyzoite** describing that it is developing at low speed in contrast to ► **tachyzoites** = quickly reproducing stages of the same species found, e.g., in macrophages.

Cytauxzoon

Synonyms

Theileria

Cytauxzoon felis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *kytos* = cell, *auxe* = growth, *zoon* = animal.

Although it was recently suggested that *C. felis* is a ► *Theileria* species (e.g., *T. taurotragi*-like), its systematic position remains unsolved. However, it should be considered in any way as piroplasmic parasite of domestic and wild cats (mainly spreading in North America). It penetrates red blood cells as well as cells inside

lymph nodes and leads to a ► [theileriasis](#)-like disease with rapidly progressing symptoms such as fever, inappetance, anorexia, lethargy, mild pneumonia and anemia, dyspnea, icterus, and often sudden death after short time infection. Vectors are the American tick species *Amblyomma americanum* (= American dog tick) and *Dermacentor variabilis* (= lone star tick). Natural hosts are, e.g., bob cats (*Lynx rufus*) but probably also other related animals. There exists neither a vaccine nor a reliable chemotherapy. Protection can just become achieved by use of insecticides (10 % imidacloprid/4.5 % flumethrin) in collars.

Further Reading

Cytauxzoon taurotragi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *kytos* = cell; *auxe* = growth; *zoon* = animal; Latin: *taurus* = bull; *tragus* = buck. This name is a synonym of a ► [Theileria](#) species (*T. taurotragi*).

Cytauxzoonosis

Disease of domestic cats and bobcats (Reservoir) in the USA due to infection with ► [Cytauxzoon felis](#), a 2 µm-sized piroplasm parasite of lymphocytes and erythrocytes being transmitted by

► [ticks](#) (e.g., *Dermacentor variabilis*). Some authors believe that ► [Cytauxzoon](#) is synonymous to ► [Theileria](#). The disease shows rapidly progressing clinical signs such as high fever, icterus, lethargy, shortly followed by death.

Therapy

Unknown, try ► [Theileriacidal Drugs](#).

Cythioate

Chemical Class

Organophosphorous compounds (monothiophosphate).

Mode of Action

Acetylcholine esterase inhibitor. ► [Ectoparasitocides: Agonists and Antagonists of Cholinergic Transmission](#).

Cytoadherence

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Infected erythrocytes, e.g., of *Plasmodium falciparum* become attached to the walls of blood vessels in different organs. This leads to blocking of the blood stream in small vessels and following dysfunctions of organs. This attachment is due to the formation of the parasite surface protein *Plasmodium falciparum* erythrocyte membrane protein 1 (PfEMP1).

Cytoadhesion

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the phenomenon when *Plasmodium* infected erythrocytes become firmly attached to the endothelium of blood vessels or to other cells inside the blood by help of host cell receptors and parasite ligands. This activity may introduce blocking of blood vessels with fatal outcome.

Further Reading

Cytoadhesion/Cytoadherence

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

In the case of infections with *Plasmodium falciparum*, infected red blood cells are sequestered away from the peripheral blood circulation by their adhesion at the walls inside microvascular blood vessels, which thus become often completely blocked for normal blood transportation. This adhesion is mediated by a protein included in the cell membrane of *P. falciparum* infected erythrocyte (PfEMP1). Similar effects are seen in *P. reichenowi* infected red blood cells although *P. reichenowi* and *P. falciparum* were thought to have divided themselves from each other about 5–7 million years ago (Escalante et al. 1998). PfEMP1 is presented at the surface

of the infected red blood cells at places which are called ► **knobs**. These tiny protrusions, which are clearly visible using scanning electron microscopy, are largely composed of the “knob-associated-histidine-rich protein (KAHRP)” (Kilejia 1979).

Since early stages of *P. falciparum* gametocytes are also sequestered away from peripheral circulation of the red blood cells, but lack knobs, apparently another mechanism seem to work it out. It is discussed that they adhere with a lower efficiency than the asexual stages bearing erythrocytes, but achieve to hide at sites of reduced vascular flow, so that they are not found in blood taken from peripheral vessels and investigated by blood smears or thick drop methods.

Cytoskeleton

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The network of protein filaments and microtubules in the ► [cytoplasm](#) is called cytoskeleton.

Contractile elements are responsible for the cytoplasmic flow and these include ► [actin](#) filaments with a diameter of ~ 6 nm. These filaments are composed of a double chain of globular bodies. Cytoskeletons may also contain 10 nm filaments or intermediate filaments which, to date, have been found only in the cells of higher vertebrates. The various types of filaments are organized into the microtubules of the cytoskeleton. The tubules have an outer diameter of 25 nm and an inner diameter of 15 nm. They are composed of protofilaments that are visible in cross-sections. The protofilaments consist of α - and β -tubulin elements in a helical arrangement. The microtubules are polymerized at particular points called microtubule organizing centers (► [MTOCs](#)). These centers exist at centromeres, ► [centrioles](#), and at certain places in membranes. They also occur as constituents of ► [flagella](#) and ► [cilia](#) (► [Locomotory Systems](#), ► [Flagella](#)).

The processes that bring about motility of the cytoplasm are well documented for metazoan cells, but for ► [Protozoa](#) these processes are still poorly understood (► [Apicomplexa/Motility](#)). In all cases, it is probably the aggregation of ► [actin](#) with ► [myosin](#) and tropomyosin to form an actomyosin complex that leads to movement, as proposed in the sliding filament model of Huxley and Hanson. This ATP-dependent system may produce relatively rapid movements, as occur in ameba (20 μ m per second), and in the sporozoites and merozoites of sporozoans. In addition to the cytoskeletal system, most parasitic protozoa have developed unique skeletal elements composed of

combinations of the usual cytoskeleton elements. These structures include the following:

- The ► [subpellicular microtubules](#) of trypanosomes and the motile stages of the ► [Coccidia](#) (► [Pellicle](#), ► [Apicomplexa](#)).
- The kinetodesmal fibrils of ciliates.
- The bundles of cytoplasmic microtubules in gamonts of ► [piroplasms](#) (Gametes).
- The combined microtubules and filaments observed in the ventral disc of the diplomonadids (► [Giardia lamblia](#)).
- The crystalloid protein densifications that occur below the membrane of giardial ► [trophozoites](#), at the apex of eimerian ► [microgametes](#) (Gametes) and in the gamonts of piroplasms (Gametes).
- The ► [axostyles](#) and pelta, occurring prominently in the ► [trichomonads](#) and consisting of one or more parallel rows of microtubules (► [Trichomonadida](#)).
- The ► [costa](#) and parabasal filaments, the filamentous, sometimes striated elements (► [Mitochondria](#), ► [Trichomonadida](#)) that line the recurrent flagellum or the ► [Golgi apparatus](#) in trichomonads.
- The ► [paraxial rods](#), which consist of a network of microfilaments that run along the axonemal microtubules of the ► [flagella](#) of ► [Kinetoplastida](#) (► [Pellicle](#), ► [Trypanosoma](#), ► [Flagella](#)).
- The ► [conoids](#), which are found in the motile stages of some Coccidia, such as ► [Eimeria](#), ► [Sarcocystis](#), and *Toxoplasma* (► [Pellicle](#), ► [Kinete](#)), but which are always absent from the corresponding stages of haemosporidians (e.g., ► [Plasmodium](#), piroplasms).

Cytostome

Cell mouth (► [Micropore](#) of ► [Apicomplexa](#)). Special place for the uptake of food developed by many ► [Protozoa](#) (► [Endocytosis](#), Figs. 1 and 2).

D

Dactylogyrus intermedius

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Monogenean parasite of the goldfish (*Carassus auratus*)

Dactylosoma

Genus of babesoid parasites in red blood cells of amphibian animals.

Dahomey Gap

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This zone separates the forest zone that covers much of the south of the ► *Loa loa* endemic region into two separate parts.

Daily Biting Rate (DBR)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Daily biting rate of insects as vectors of parasites or other agents of diseases.

Daily Visiting Frequency

Presence (man × hour) at places, where vectors may transmit agents of disease. This factor measures the population at risk for an infection.

DALY

Disability addjusted life years (due to parasites) represents a measure of disease burden. In the case of ► *malaria* the number is around 40 million.

Danger Index

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The danger index (modified according to Mihály 1967) is of course an artificial collection of data which allow, however, a survey of the dangers that may be connected with the occurrence of flies (at least in larger numbers) at certain places under some given conditions.

The danger index $D = (a + b + c + d) \times (e + f + g) \times m$ thus gives a relative grade of the risks that are induced for animal and human health if there are considerable amounts of flies close to humans and animals. The different variables a – g and m have the gradings 0, 0.5, or 1. Thus, the highest danger index is 12. The different variables (a – g , m) are based on the following definitions:

$a, b, c:$	Grade 1 is given, when both females and males visit human or animal feces for feeding and/or egg deposition
$d:$	Grade 1 is given, if these species visit wounds and such infectious “juices”
$e:$	Grade 1 is given, if the species is eusynanthropic (i.e., mainly based in human surroundings), and grade 0.5 is given, if the species is hemisynanthropic (i.e., may also exist in larger numbers in the wider world)
$f:$	Grade 1 is given, if the flies set down on milk or other human food
$g:$	Grade 1 is given, if the flies also set down on fruits
$m:$	Grade 1 is given, if the fly is not bigger than <i>Musca domestica</i>

As examples for comparison, the danger indices (D) of several licking fly species were given below. In that of *Stomoxys* the index is misleading: $D = (a + b + c + d) \times (e + f + g) \times m$

Fly species	a	b	c	d	e	f	g	m	D
<i>Calliphora vicina</i>	1	1	1	1	1	1	1	1	12
<i>Calliphopra vomitoria</i>	1	1	1	1	1	1	1	1	12

(continued)

Fly species	a	b	c	d	e	f	g	m	D
<i>Fannia canicularis</i>	1	1	1	1	1	1	1	0.5	6
<i>Helina reversio</i>	1	1	1	0	0.5	0	0	0.5	0.75
<i>Lucilia caesar</i>	1	1	1	1	1	1	1	1	12
<i>Musca domestica</i>	1	1	1	1	1	1	1	1	12
<i>Muscina pabulorum</i>	1	1	1	0	0.5	1	0	1	4.5
<i>Muscina stabulans</i>	1	1	1	0	1	1	0	1	6
<i>Mydaea ancilla</i>	1	1	1	0	0.5	0	0	1	1.5
<i>Mydaea urbana</i>	1	1	1	0	0.5	0	0	1	1.5
<i>Phaonia errans</i>	1	1	1	0	0.5	0	0	1	1.5
<i>Polietes lardaria</i>	1	1	1	0	0.5	0	0	0.5	0.75
<i>Pollenia angustigena</i>	1	1	1	0	0.5	0	0	0.5	0.75
<i>Sarcophaga carnaria</i>	1	1	1	0	0.5	1	0	1	4.5
<i>Sarcophaga argyrostoma</i>	1	1	1	0	0.5	1	0	1	4.5
<i>Stomoxys calcitrans</i>	0	0	0	1	1	0	0	1	1

Although the danger index makes some sense in the case of licking flies, it cannot be applied to bloodsucking Brachycera such as *Stomoxys calcitrans* and/or tabanids. In these cases, many of the parameters a – g do not fit for bloodsuckers and would lead to a too low danger index, which does not reflect the possible mechanical transmission of important agents of diseases (such as poliomyelitis, several bacterioses, and even worm diseases) during bloodsucking. The Table summarizes the danger indices for several – often severe – agents of diseases. The inclusion of *Stomoxys calcitrans* under the conditions given here obviously makes no sense, since its importance as a bloodsucker and mechanical vector of agents of diseases is much higher than grade 1.

Furthermore, species such as *Sarcophaga carnaria* which may enter also tissues are underestimated in this danger index system. On the other hand, species with a low danger index

may also be successful vectors of severe agents, if their body comes into contact with a source that contains a significantly high number of pathogens.

Thus, in any case, fly control in houses and animal stables must have high priority, since the health of humans and animals is endangered by mass occurrence of flies.

Darwin, Charles Robert

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Charles Darwin was an English naturalist and geologist. Although he studied theology and reached the Anglican ordi degree in 1831, natural sciences attracted him from the very beginning of his studies. This approach was intensified when he read Paley's *Natural Theology* pointing out that God had designed anything on earth (living or dead). On the other side, contemporian literature was full of reports on expeditions into the natural forests in the tropics (e.g., Alexander von Humboldt's South American travel reports). Darwin was so excited that he took part in courses on geology and other natural sciences. The chance to join on own costs the around the world expedition of the sailing vessel Beagle under Captain Fitzgerald (1831–1835) changed his life. Starting merely as a collector of specimens than as an interpreter of contexts or phenomena, the insights of this travel increased constantly his doubts in the official divine creation theory. Feeling to be torn between the Christian base of his life and that of the English society on one side and his increasing insights on an evolution in nature, Darwin kept back his insights for years. Only when Alfred Russel Wallace sent him in the year 1858 a proposed publication on ideas identical to his own, that the struggle for existence of species in a given biotope effects an artificial selection of those species which fit best to the given conditions, Darwin started finally to write down his insights in this field by publishing the famous book *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* after short articles had been published by him and Wallace in the year 1858 without obtaining much attention in the public.

This book became famous at once, and "Darwinism" changed the world but also initiated deep

inner pressures in Darwin’s feeling to have delivered the base of atheism for himself and large parts of the world. He was strongly attacked by the public, and caricatures showed him close to monkeys (Fig. 1). On the other side, his strictly biological theory, which is proven today by modern molecular biological methods, was quickly misused by protagonists of the so-called social Darwinism and by eugenic movements promoting that some “human races” are better than others. His deep doubts in the existence of a “kind god” can be seen in the lines he wrote to the American naturalist Asa Gray:

I own cannot see as plainly as others do, and as I should wish to do, evidence of design and beneficence on all side of us. There seems to me too much misery in the world. I cannot persuade myself that a beneficent and omnipotent God would have designedly created the Ichneumonidae with

the express intention of their feeding within the living bodies of caterpillars, or that a cat should play with mice.

The adaption of parasites to the biology of their hosts and to the environment proves all ideas involved from Darwin’s and Wallace’s insights (Fig. 2).

Demodex folliculorum

Name

Greek: *demas* = body, *dex* = stretched.

Synonyms

Follicle mites, sebaceum gland mites.

Classification

Subclass – Acari, Order – Acariformes,
Suborder – Prostigmata.

Life Cycle

D. folliculorum mites are 0.4 mm long (Fig. 1) and live in the follicles of the hair. *D. brevis* lives in the sebaceous glands with a similar size. Adults have a lifespan of about 5 days, while the development of the whole generation needs about 15 days (► [Mites](#)).

***Demodex folliculorum*,**

Demodex Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *demos* = body; *dex* = stretched. Latin: *folliculus* = small bladder; *brevis* = short. English: follicle mites.

Geographic Distribution/Epidemiology

Worldwide, main transmission between mother and newborn babies; practically all humans and animals are infected, but symptoms are rare except for immunocompromised persons.

Demodex Species, Table 1 Life cycle data of the *Demodex* species of humans and animals

Species	Hosts	Body size (μm)	Egg size (μm)	Main sites of infection
<i>D. canis</i>	Dogs	0.15–0.25	70–90 × 25	Head, anterior legs, belly, breast sides
<i>D. felis</i>	Cats	0.15–0.25	70–90	Head
<i>D. suis</i>	Pigs	0.27	80 × 25	Snout, eyelids, belly, inner side of legs
<i>D. bovis</i>	Cattle	0.4	80 × 50	Head, shoulder, anterior breast
<i>D. caprae</i>	Goats	0.45	80 × 50	Head, shoulder, anterior breast
<i>D. ovis</i>	Sheep	0.45	80 × 50	Head, shoulder, anterior breast
<i>D. equi</i>	Horses	0.4	60–80 × 40	Eyelids
<i>D. folliculorum</i>	Humans	0.4	70 × 40	Many places
<i>D. brevis</i>	Humans	0.25	70 × 40	Many places

Biology/Morphology

In humans and animals, different species are described. The human mites *D. folliculorum* and *D. brevis* are tiny, long-stretched mites, which measure 0.3–0.4 μm (*D. folliculorum*) and 0.25 μm (*D. brevis*) in length. *D. folliculorum* feeds on the epithelium of the hair bulb, while *D. brevis* feeds on the interior of the tallow glands. The adult mites are short living (~5 days), while their larval development takes 10 days. All in all, there is a very short sequence of the generations, which is due to the limited space at the hair base. Transmission occurs by body contact.

In animals, the following species are described among others (see Table 1):

D. canis (common in dogs), *D. felis* (syn. *cati*) (rarely in cats), *D. bovis*, *D. caprae*, *D. ovis* (in ruminants), *D. equi caballi* (in horses), *D. suis* (pigs).

After a development of ~10 days from eggs via six-legged larva I to eight-legged protonymph I and II, the adults reach maturity after about 30 days in total. Their individual life span seems to be somewhat longer than in the human species. A diagrammatic representation of the life cycle stages is presented in the chapter ► [Mites](#) (Figs. 1, 2, 3, and 4).

Symptoms of Disease

Rosacea, alopecia, pyoderma, lupus miliaris, blepharitis, dermatitis, macropapulosis, lesions depending on the grade of infection.

Demodex Species, Fig. 1 *Demodex folliculorum*; SEM of an adult mite, from ventral; note the eight short legs

Diagnosis

Squeezing of skin in reddish, inflamed regions. The material has to be placed into a drop of concentrated milk acid and microscopically checked for mite stages.

Demodex Species, Fig. 2 Diagrammatic representation of the life cycle of *D. folliculorum* and other important mites

Demodex Species, Fig. 3 Section through the skin of a dog with several *Demodex* mites

Infection Mode

Body contact: mainly mother to baby or contact with highly infected hosts (e.g., AIDS patients in clinics).

Prophylaxis

Body care; in animals: regular treatment with ectoparasitica; exclusion of heavily infected animal from breeding.

Demodex Species, Fig. 4 Dogs showing symptoms of demodicosis. (a) local demodicosis; (b, c) generalized demodicosis

Incubation Period

About 2 weeks, if symptoms occur at all in low-graded infections.

Prepatency

Two weeks.

Patency

Years, due to repeated self-infections.

Therapy

Ivermectin (i.e., Stromectol® for humans).

Demodex Species of Animals

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Synonyms

Follicle mites; Sebaceous gland mites

Name

Greek: *demos* = body; *dex* = stretched.
The term refers to the long stretched body.
English, follicle mite; French, acare folliculaire.

Life Cycle

These strictly host-specific mites live in the follicle and/or in the adjacent glands, as adult females reach a size of 0.2–0.3 mm (males: 0.25 mm) in length and appear cigarillo-like with short, stumpy feet (Fig. 1). Their chewing mouthparts are stumpy, too. Females depone whitish eggs at their feeding sites. Via 1–2 six-legged larval stages and 2 eight-legged nymph stages, the mites reach maturity. Transmission from a female host to its baby occurs during the first days of life by body contact. Copulation proceeds on the skin surface inside the hair channel. Males die afterwards and females enter the follicle where they depone about 20 citron-like eggs (80 × 25 µm). The whole individual development takes about

3 weeks. Outside of the body, these mites cannot survive. Thus, they are permanent stationary parasites.

Disease

Except for dogs, which may suffer severely from ► *Demodex canis*, most of the infections of other animals (Table 1) remain inapparent, although prevalence rates (up to 85 %) may occur.

Diagnosis

Squeezing of an infected region of the skin until fluid drops on to the glass slide or is smeared thereon (application of skin scraping material). This material is degenerated by use of the so-called KOH-method (incubation of the material in a 10 % KOH solution and short heating).

Therapy

There are several possibilities depending on the type and grade of the clinical symptoms.

- 1. Weekly washing with a 0.05 % solution of amitraz/metaflumizone (ProMeris Duo®)

Demodex Species of Animals, Fig. 1 Scanning electron micrograph of *Demodex* specimens isolated from hosts after KOH treatment of material obtained by skin scraping

Dengue Fever History

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Dengue fever (due to 4 serotypes DENV1-V4) was first mentioned in the period between 265 and 420 PC in a Chinese encyclopedia, then it occurred widely in epidemics during 1635 and 1699 in the Caribbean region, Asia, Africa, and North America. The so-called Breakbone fever epidemics in Philadelphia (1779–1780) was evidently also Dengue. Today 2–5 billions of humans are endangered in the tropics and subtropics (especially in South East Asia). It is concluded that about 50–100 million new cases occur per year. Vectors are *Aedes* species (e.g., *Aedes aegypti*, *A. albopictus*).

Dengue viruses (DENV) are single-stranded, non-segmented ribonucleic acid (RNA),

emerging, mosquito-borne flaviviruses, and the causative agents of dengue fever (DF), one of the world's emerging infectious diseases, which is also known as breakbone fever and dengue hemorrhagic fever (DHF). In tropical and subtropical regions (it is endemic in most countries of Southern and Southeast Asia, the Western Pacific regions, Central and South America, the Caribbean and Africa), 50–100 million people are infected in the developing world per year, and the numbers are rising globally. Local transmission of dengue in Europe was reported for the first time in 2010 (in France and Croatia), and imported cases were detected in three other European countries. Over 2,000 cases were reported from a 2012 outbreak on Madeira Islands of Portugal, which resulted in imported cases in ten other countries in Europe apart from mainland Portugal. Of these infections, several hundred thousands progress to dengue hemorrhagic fever, which is life-threatening and show together with dengue shock syndrome (DSS) a mortality rate of 25,000 per year. Typical symptoms are fever, severe headache, prostration, orbital pain, and general indisposition. Dengue hemorrhagic fever/dengue shock syndrome is characterized by four major clinical manifestations – high fever, hemorrhagic phenomena, often hepatomegaly, and circulatory failure. The characteristic hemorrhagic manifestations of DHF result due to capillary leakage. The first days present similar to dengue fever in regard to the symptoms, but 4–7 days after the diseases' onset, the development of plasma leakage can be observed. The first signs are often abdominal pain, vomiting, restlessness, and changing level of consciousness. Dengue shock syndrome is characterized by a rapid weak pulse with profound hypotension and shows a mortality rate of may be as high as 40 %. Primary vectors are species of the mosquito genus *Aedes* (*Aedes aegypti* and *Aedes albopictus*), with *A. aegypti* being the principal vector. Due to several introductions, these mosquitoes are found worldwide in the tropics and subtropics. The members of this species are daytime feeders and well adapted to an urban environment in regard to their breeding habits. Eggs are laid in small water containers like tires, cans, and water jars in human

Dengue Fever Virus Generalities, Fig. 1 Dengue fever virus: transmission risk areas

neighborhood. Because of their anthropophilic biting behavior, the disease can be transmitted readily by the females, as they are also known for multiple interrupted feedings. An additional problem is that in many dengue fever-endemic areas, no policies for mosquito control exist or are far from being successful (Fig. 1).

In humans, the incubation period for the disease is 4 up to 10 days. So far, the virus has been detected worldwide in tropical and subtropical regions, especially in Southeast and South Asia and in Central and South America with an ongoing transmission risk in Africa. The first reported cases occurred at the end of the eighteenth century in Asia, Africa, and North America, while dengue hemorrhagic fever first occurred in the 1950s in the Philippines and Thailand. In the first half of the twentieth century in Europe (Austria, Greece, Italy, and Spain), the virus caused epidemics. Infections increased worldwide during the last decades, and nearly 2.5 billion people about 40 % of the world population live in dengue-risk zones which ranks dengue fever as one of the most important mosquito-borne disease in the world. The dengue virus complex consists of four distinct but related viruses (serotypes): DEN-1, DEN-2, DEN-3, and

DEN-4. The different dengue viruses display antibody epitopes. Some of these are unique to each serotype, and others are shared between various serotypes. After the first dengue virus infection, patients develop strong antibody responses which cross-react with the four serotypes. Anyway, although there is a cross-reactivity, the developed antibodies only prevent reinfection by the same (homologous) serotype, and susceptibility to a second infection by another (heterologous) serotype is still given. People who are infected the second time with dengue of a new serotype face a much greater risk to develop dengue hemorrhagic fever. This is an indication that a preexisting immunity to dengue virus can exacerbate the disease. Antibody-dependent enhancement (ADE) of dengue virus is the most widely supported theory for the higher risk to develop dengue hemorrhagic fever with a second infection. The antibody response to dengue virus infection is complex and has the potential of both: to benefit or harm the host. Immigrants and persons who visit people in dengue-endemic areas face a greater risk to get dengue hemorrhagic fever than general travelers, while dengue shock syndrome in travelers is uncommon. Anyway, travelers who revisit the same place face the risk of

dengue hemorrhagic fever. Additionally, there is a risk that travelers spread the disease to previously dengue-free countries or areas through imported cases.

Dengue can occur in two transmission cycles: a sylvatic (enzootic) and an urban endemic/epidemic one. The sylvatic cycle involves nonhuman primates and forest mosquito species of the genus *Aedes* and has been documented for West Africa and peninsular Malaysia. The human cycle involves *A. aegypti* and *A. albopictus* and can be found in a wide variety of environments throughout the tropics and subtropics. In the human cycle, humans are the only known reservoir hosts as well as amplification hosts. This circumstance is a unique host usage pattern among arboviruses. As the dengue vectors spread, the possibility that transmission could be possible in the future in previously non-endemic areas has to be considered. In combination with the introduction of dengue viruses by returning tourists, this poses a health threat for Europe. So far, a number of dengue vaccines are under development including live attenuated dengue vaccines, which entered phase III human trials. To prevent infection, protective measures such as using mosquito repellents and wearing clothes which minimize skin exposure are the methods of choice. Because of the mosquitoes' anthropophilic habits, the risk of acquiring infection may be lower in many preferred travel destinations, such as beaches, hotels with well-kept grounds, and jungle areas, than in rural and urban areas which are inhabited by lower-income groups lacking effective mosquito control. So far, there is no special treatment or a vaccine available; the only method to control or prevent the transmission of dengue virus is to combat vector mosquitoes.

Dengue fever is diagnosed by virus isolation in cell cultures, nucleic acid detection by PCR, viral antigen detection, or specific antibodies. The most accurate methods are virus isolation and nucleic acid; due to their greater cost, these tests are not widely available. In 2012, a RT-PCR test, called the CDC DENV-1-4 Real-Time RT-PCR Assay, was introduced and can run on equipment used to diagnose influenza; this is likely to improve access to PCR-based diagnosis.

The mentioned laboratory tests are only of diagnostic value during the acute phase of the illness with the exception of serology.

Tests for dengue virus-specific antibodies, types IgG and IgM, can be useful in confirming a diagnosis in the later stages of the infection. Both IgG and IgM are produced after 5–7 days. The highest levels (titers) of IgM are detected following a primary infection, but IgM is also produced in reinfection. IgM becomes undetectable 30–90 days after a primary infection but earlier following reinfections. IgG, by contrast, remains detectable for over 60 years and, in the absence of symptoms, is a useful indicator of past infection. After a primary infection, IgG reaches peak levels in the blood after 14–21 days. In subsequent reinfections, levels peak earlier, and the titers are usually higher. Both IgG and IgM provide protective immunity to the infecting serotype of the virus. The laboratory test for IgG and IgM antibodies can cross-react with other flaviviruses and may result in a false-positive after recent infections.

Dengue viruses (DENV) are single-stranded, nonsegmented ribonucleic acid (RNA), emerging, mosquito-borne flaviviruses, and the causative agents of dengue fever (DF), one of the world's

emerging infectious diseases, which is also known as breakbone fever and dengue hemorrhagic fever (DHF). In tropical and subtropical regions (it is endemic in most countries of Southern and South-east Asia, the Western Pacific regions, Central and South America, the Caribbean, and Africa) (Fig. 1), 50–100 million people are infected in the developing world per year, and the numbers are rising globally. Local transmission of dengue in Europe was reported for the first time in 2010 (in France and Croatia), and imported cases were detected in three other European countries. Over 2,000 cases were reported from a 2012 outbreak on Madeira islands of Portugal, which resulted in imported cases in ten other countries in Europe apart from mainland Portugal. Of these infections, several hundred thousands progress to dengue hemorrhagic fever, which is life threatening and shows together with dengue shock syndrome (DSS) a mortality rate of 25,000 per year. Typical symptoms are fever, severe headache, prostration, orbital pain, and general indisposition. Dengue hemorrhagic fever/dengue shock syndrome is characterized by four major clinical manifestations – high fever, hemorrhagic phenomena, often hepatomegaly, and circulatory

Dengue Virus, Fig. 1 Dengue fever virus: transmission risk areas

failure. The characteristic hemorrhagic manifestations of DHF result due to capillary leakage. The first days present similar to dengue fever in regard to symptoms, but 4–7 days after the diseases' onset, the developing of plasma leakage can be observed. The first signs are often abdominal pain, vomiting, restlessness, and changing level of consciousness. Dengue shock syndrome is characterized by a rapid weak pulse with profound hypotension and shows a mortality rate of may be as high as 40 %. Primary vectors are species of the mosquito genus *Aedes* (*Aedes aegypti* and *Aedes albopictus*), with *A. aegypti* being the principal vector. Due to several introductions these mosquitoes are found worldwide in the tropics and subtropics. The members of this species are daytime feeders and well adapted to an urban environment in regard to their breeding habits. Eggs are laid in small water containers like tires, cans, and water jars in human neighborhood. Because of their anthropophilic biting behavior, the disease can be transmitted readily by the females, as they are also known for multiple interrupted feedings. An additional problem is that in many dengue fever endemic areas, policies for mosquito control do not exist or are far from being successful.

In humans, the incubation period for the disease is 4 up to 10 days. So far, the virus has been detected worldwide in tropical and subtropical regions, especially in Southeast and South Asia and in Central and South America with an ongoing transmission risk in Africa. The first reported cases occurred at the end of the eighteenth century in Asia, Africa, and North America, while dengue hemorrhagic fever first occurred in the 1950s in the Philippines and Thailand. In the first half of the twentieth century in Europe (Austria, Greece, Italy, and Spain), the virus caused epidemics. Infections increased worldwide during the last decades, and nearly 2.5 billion people, about 40 % of the world population, live in dengue risk zones which ranks dengue fever as one of the most important mosquito-borne diseases in the world. The dengue virus complex consists of four distinct but related viruses (serotypes): DEN-1, DEN-2, DEN-3, and DEN-4. The different dengue viruses display antibody epitopes.

Some of these are unique to each serotype, and others are shared between various serotypes. After the first dengue virus infection, patients develop strong antibody responses which cross-react with the four serotypes. Anyway, although there is a cross-reactivity, the developed antibodies only prevent reinfection by the same (homologous) serotype, and susceptibility to a second infection by another (heterologous) serotype is still given. People who are infected the second time with dengue of a new serotype face a much greater risk of developing dengue hemorrhagic fever. This is an indication that a preexisting immunity to dengue virus can exacerbate the disease. Antibody-dependent enhancement (ADE) of dengue virus is the most widely supported theory for the higher risk of developing dengue hemorrhagic fever with a second infection. The antibody response to dengue virus infection is complex and has the potential to both benefit and harm the host. Immigrants and persons who visit people in dengue-endemic areas face a greater risk to get dengue hemorrhagic fever than general travelers, while dengue shock syndrome in travelers is uncommon. Anyway, travelers who revisit the same place face the risk of having dengue hemorrhagic fever. Additionally there is a risk for travelers to spread the disease to previously dengue-free countries or areas through imported cases.

Dengue can occur in two transmission cycles: a sylvatic (enzootic) and an urban endemic/epidemic one. The sylvatic cycle involves nonhuman primates and forest mosquito species of the genus *Aedes* and has been documented for West Africa and peninsular Malaysia. The human cycle involves *Ae. aegypti* and *Ae. albopictus* and can be found in a wide variety of environments throughout the tropics and subtropics. In the human cycle, humans are the only known reservoir hosts as well as amplification hosts. This circumstance is a unique host usage pattern among arboviruses. As the dengue vectors spread, the possibility that transmission could be possible in the future in previously non-endemic areas has to be considered. In combination with the introduction of dengue viruses by returning tourists, this poses a health threat for Europe. So far, a

number of dengue vaccines are under development including live-attenuated dengue vaccines, which entered phase III human trials. To prevent infection, protective measures such as using mosquito repellents and wearing clothes which minimize skin exposure are the methods of choice. Because of the mosquito anthropophilic habits, the risk of acquiring infection may be lower in many preferred travel destinations, such as beaches, hotels with well-kept grounds, and jungle areas, than in rural and urban areas which are inhabited by lower-income groups lacking effective mosquito control. So far there is no special treatment or a vaccine available; the only method to control or prevent the transmission of dengue virus is to combat vector mosquitoes.

Dengue fever is diagnosed by virus isolation in cell cultures, nucleic acid detection by PCR, viral antigen detection, or specific antibodies. The most accurate methods are virus isolation and nucleic acid; due to their greater cost, these tests are not widely available. In 2012 a RT-PCR test, called the CDC DENV-1-4 Real Time RT-PCR Assay, was introduced and can run on equipment used to diagnose influenza; this is likely to improve access to PCR-based diagnosis.

The mentioned laboratory tests are only of diagnostic value during the acute phase of the illness with the exception of serology.

Tests for dengue virus-specific antibodies, types IgG and IgM, can be useful in confirming a diagnosis in the later stages of the infection. Both IgG and IgM are produced after 5–7 days. The highest levels (titers) of IgM are detected following a primary infection, but IgM is also produced in reinfection. IgM becomes undetectable 30–90 days after a primary infection, but earlier following reinfections. IgG, by contrast, remains detectable for over 60 years and, in the absence of symptoms, is a useful indicator of past infection. After a primary infection IgG reaches peak levels in the blood after 14–21 days. In subsequent reinfections, levels peak earlier and the titers are usually higher. Both IgG and IgM provide protective immunity to the infecting serotype of the virus. The laboratory test for IgG and IgM antibodies can cross-

react with other flaviviruses and may result in a false positive after recent infections.

Dense Bodies

The dense bodies occur in the motile stages such as sporozoites, merozoites (inclusive zoites, brady- and ► **tachyzoites** and are found in front of the nucleus among the ► **micronemes** and the bulbous ends of the club-shaped ► **rhoptries** (► **Merozoite**, Fig. 1). They appear spherical, are membrane-bound and have an electron dense interior. Their diameters are rather similar in most species, reaching about 0.2 µm at the maximum. Just after penetration of the parasitic stages into a host cell, the contents of the dense bodies, which consist of at least six different proteins (enzymes?, GRA 1–6), are excreted into the surrounding ► **parasitophorous vacuole** and are found also on the outer surface of the parasite. It is thought that the contents of the dense bodies protect the

parasite, which starts development, from the attack of the host cell's digestive enzymes.

Deoxynucleotides

Heinz Mehlhorn¹ and Peter Köhler²

¹Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

²Institute for Parasitology, University of Zürich, Zürich, Switzerland

Deoxyribonucleotides, the building blocks of DNA, are derived in most parasitic protozoa and in helminths, as in mammalian cells, primarily from the corresponding ribonucleotides as catalyzed by ribonucleotide reductase. Some protozoa, including *Entamoeba*, *Giardia*, and ► *Trichomonas vaginalis*, lack ribonucleotide reductase and, thus, have to meet their deoxynucleotide requirements by salvage pathways. The synthesis of deoxythymidine nucleotides, which are required for DNA synthesis, is initiated by the conversion of dUMP to dTMP (Fig. 1). In this process, the necessary methylation of the pyrimidine ring is catalyzed by the tetrahydrofolate-dependent enzyme thymidylate synthase (TS). In several protozoan species,

including the apicomplexans, *Leishmania major* and *Trypanosoma cruzi*, TS is unusual in that it differs in its structural and kinetic properties from the corresponding mammalian enzyme and exists as a bifunctional protein associated with dihydrofolate reductase (DHFR) (Fig. 1). In ► *helminth* and mammalian cells, both the synthase and reductase activities are attributed to separate enzymes. The greater susceptibility of the parasite DHFR domain of the bifunctional enzyme toward inhibition by antifolate drugs than the mammalian enzyme and the absolute dependence on the *de novo* synthesis for dTMP forms the basis for the selective toxicity of these compounds against apicomplexan parasites. The conversion of nucleoside mono- and diphosphates to the corresponding triphosphates is carried out in parasites primarily by nucleotide kinases as is common to most living organisms. Because of the lack of TS in *Entamoeba*, *Giardia*, and trichomonads, these organisms are unable to synthesize dTMP from dUMP and rely entirely on the host for this deoxynucleotide.

Dermacentor

Genus of 3-host ixodid ticks, e.g., *D. reticulatus* parasitic in dogs (► *Dermacentor reticulatus*, Fig. 1).

Deoxynucleotides, Fig. 1 The biosynthesis of deoxythymidylate (dTMP) in parasitic protozoa. TS/DHFR, thymidylate synthase/dihydrofolate reductase complex. MeTHF (N⁵, N¹⁰-methylenetetrahydrofolate) is produced from THF by the action of serine hydroxymethyltransferase (*). DHF dihydrofolate, THF tetrahydrofolate. Protozoan TS and DHFR exist as a single bifunctional enzyme. Amitochondriate protozoa lack TS and are therefore unable to produce dTMP from dUMP

Dermacentor marginatus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Sheep tick in Germany, that also sucks on cattle, man, and dogs, where it may transmit *Babesia canis* (Fig. 1).

***Dermacentor marginatus*,**

Fig. 1 Macrophoto of an unsucked female and diagrammatic representation of a unsucked male and a fully sucked female

***Dermacentor nuttalli* Olenner, 1929**

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This ixodid tick is widely spread in the Palearctic faunal region in Eastern Siberia, Mongolia, and China. The specimens parasitize commonly animals of livestock, but are also aggressive to humans. Since *D. nuttalli* is an important vector of the agents of Tularaemia, of the North Asian tick-borne rickettsiosis, anaplasmosis, brucellosis, and Q-fever, protection of animals and humans is highly required.

Dermacentor reticulatus

Name

Greek: *derma* = skin, *centeo* = biting; Latin: *reticulum* = small net (English = ornate cow tick).

Synonyms

Formerly it was thought that *D. marginatus* (Sheep tick) is identical with *D. reticulatus*.

Life Cycle

This 3-host tick (Fig. 1) is characteristic for southern Europe, but now enlarges its biotopes considerably northward; e.g., it is found in almost all German regions (perhaps a reaction to global warming). Larvae and nymphs feed on rodents, mice, rabbits, and birds, while adult stages attack larger animals (e.g., cattle, deer, horse, dogs) and humans. This species involves, obligatorily, three hosts in its life cycle, while other *Dermacentor* spp. (e.g., *D. albopictus*,

D. venustus = *Anocentor* = *D. nitens*) may be 1-host ticks which molt on their hosts. The development of *D. reticulatus* in the egg takes 14–21 days, sucking as larva needs 2–6 days and molting takes 14 days on the ground to develop into the nymph. The nymphs feed for about 5 days on a new host and after dropping down to the ground they develop by molting within 12–14 days to adults, which can starve for up to 545 days before catching a new host. Thus there may be several genera within one season, if the larva, nymph, and adult are successful in catching a host. Since females lay up to 4,500 eggs and often two

generations may occur per year, their spreading is rather quick. The unfed females are 4.5–5.5 mm long, the fed ones up to 1.5 cm.

Transmission

Besides of considerable blood loss, this species can harm its hosts by transmission of severe agents of disease (e.g., theileriosis of horses, babesiosis of dogs, spotted fever, borreliosis, arbovirosis, tularaemia).

Dermacentor reticulatus, Fig. 1 LM of an adult female of *Dermacentor reticulatus* luring on grass

Dermacentor Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: *derma* = skin. Greek: *centeo* = bite.
Latin: *margo* = border; *reticulum* = small net.

Dermacentor Species, Table 1 European *Dermacentor* species and their function as vectors

Species	Stages in life cycle	Hosts of larvae and nymphs	Hosts of adults	Vectorship of agents of diseases
<i>Dermacentor reticulatus</i> Ornate cow tick	3	Small mammals, horses, birds, foxes, hare, hedgehogs	Wild and house ruminants, dogs, cats, humans	<i>Borrelia burgdorferi</i> , FSME-virus, <i>Rickettsia slovaca</i> , <i>Coxiella burnetii</i> , <i>Babesia caballi</i> , <i>Babesia canis</i> , <i>Theileria equi</i>
<i>Dermacentor marginatus</i> Ornate sheep tick	3	Small mammals, birds	Wild and house ruminants	<i>Babesia ovis</i> , <i>Coxiella burnetii</i> , FSME, <i>Anaplasma ovis</i> , <i>Francisella tularensis</i> , <i>Babesia caballi</i> , <i>Theileria equi</i>
<i>Dermacentor nuttalli</i> Ruminant tick	3	Small mammals, birds	Wild and house ruminants	Tularemia, rickettsiosis, anaplasmosis, brucellosis, Q-fever, Lyme disease, tick-borne encephalitis viruses

The genus *Dermacentor* contains 35 world-wide distributed species. The following species are important: *D. marginatus* and *D. reticulatus* in Europe; *D. silvarum* and *D. nuttalli* in Siberia, Mongolia, and China; *D. andersoni*, *D. variabilis*, *D. occidentalis*, *D. albopictus* in North America; *D. nitens* (syn. *Anocentor nitens*) in South and Central America. Life cycle and vectorship see ► *D. reticulatus* and Table 1, Figs. 1 and 2.

Dermatophytes

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *derma* = skin; *phyton* = plant.

Parasite-infested skin of cats, dogs, rabbits, and guinea pigs is often also in addition covered by developmental stages of fungi, which can be transmitted to humans, too, thus establishing a complete zoonotic transmission. Common fungi are *Microsporum canis* and *Trichogramma* sp. These stages can be treated by itraconazole, ketoconazole, and terbinafine. These products are termed as antimycotics.

Dermatotropism

Name

Latin: *derm* = skin, Greek *tropé* = turning.

Activity of parasites that wander to the skin (from in- or outside of the body).

Dermatoxys Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

There exist several species worldwide (e.g., *D. hispaniensis*, *D. proboscoidiphora*) of this genus of nematodes (family Oxyuridae), which parasitize in the intestine of rabbits and hares. For life cycle see ► [Enterobius vermicularis](#), ► [Oxyuris](#) species.

Derrengadera

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Spanish name for ► [Surra](#) (= El debab, guffar, murina) of horses and many other ruminants, pigs, carnivores, or even rodents.

Derringue Bovine

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

French name of the disease due to an infection of cattle with ► [Trypanosoma evansi](#) (mild form of

► [Surra](#)). Also a mechanical transmission by blood-licking bats is possible. Common transmission occurs during bites of tabanids like *Stomoxys* or even mosquitoes.

Desmodus rotundus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Bat species (so-called common vampire) from warm regions in South, Middle, and southern North America. See ► [Blood-Licking Bats](#).

Desmosomes

Structures attaching cells to cells or flagella to Protozoans. ► [Flagella](#).

Deutonymph

The second of up to three nymphal stages found in mites. In most cases the deutonymph molts to the adult stage. ► [Mites/Ontogeny](#).

Devescovina

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus names of trichomonadid flagellates of termites possessing three anterior flagella and a recurrent one.

Diagramma interrupta

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This tapeworm belongs to the family Ligulidae (► [Ligula intestinalis](#)), reaches as larva a length of up to 1 m in the body cavity of freshwater fish and uses waterbirds as final hosts. After oral uptake the worms reach maturity within 2 days inside the intestine of the final bird hosts.

Diamanus montanus

New World flea of the family Ceratophyllidae (Ceratophyllus, ► [Nosopsyllus](#)).

Diamidines

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Diamidines are dicatonic molecules, which bind to the DNA minor groove, whereby they inhibit one or more DNA-dependent enzymes and thus act against trypanosomes. Therefore, diamidines have been selected to become developed as new generation of antitrypanosomal drugs.

Diapause

Name

Greek: *diapausis* = interruption, rest.

This phase of inactivity during a development of arthropods may occur when the living conditions become bad, e.g., in winter. The individuum is then able to reduce considerably the processes of metabolism.

Diaptomus

First intermediate hosts (crustaceans) of ► *Diphyllobothrium* tapeworm.

Diarrhea

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek; *dia* = through; *rhein* = flowing.

This clinical feature covers the frequent and abnormally quick excretion of watery and/or slimy feces (~more than 3 times per day and the total feces weight per day exceeds more than 200 g). The reasons for these symptoms may vary considerably and may be based on diseases of the organs of the intestinal system but also on infections or on allergic reactions (Table 1). There are several subdivisions:

1. **Acute or catarrhal diarrhea:** with numerous liquid defecations per day.
2. **Chronic diarrhea:** with long-lasting symptoms.
3. **Lientric diarrhea:** with indigested food particles in stool.
4. **Profuse diarrhea:** strong, watery stool.
5. **Malassimilatory diarrhea:** food is resorbed.
6. **Mucus diarrhea:** stool contains large amounts of slimy elements.
7. **Diarrhea paradoxa:** as follow-up of an obstipation.
8. **Tropical diarrhea:** especially disease of travelers due to different agents of disease.
9. **Inflammatory diarrhea:** based on invasion and destruction of the intestinal wall by the pathogen and/or excreted toxins. This type of diarrhea is often based on infections with parasites (e.g., *Entamoeba histolytica*), bacteria (e.g., enteric salmonellas, enteroinvasive, enterohaemorrhagic *Escherichia coli*, *Campylobacter* sp.), or viruses (e.g., *Vibrio*, *Noro*) (Table 2).
10. **Noninflammatory diarrhea:** numerous watery defecations, often with convulsions (this type of disease is based on infections with parasites (e.g., *Giardia lamblia*, *Cryptosporidium* species), bacteria (enterotoxigenic *Escherichia coli*, *Bacillus cereus*), or viruses (Norwalk, *Vibrio cholera*) (Table 3).

Diarrheas of Humans

The gastrointestinal system of humans and animals has a giant surface. Even that of humans, who possess a midsized intestine between pure carnivores and exclusive plant feeders, comprises of a medium size of ~300 square meters. Therefore, it cannot be avoided that during the contact with food also damages occur along the epithelia due to toxins and/or pathogenic agents of diseases. These damages may occur due to direct interaction between agent of disease and the epithelium or due to changing of the intrainestinal milieu. The reactions of the intestine mostly are limited to a few possibilities: meteorism, obstipation, and diarrhea. With respect to diarrheas, three basic types are distinguished:

- Acute diarrhea lasting less than 2 weeks
- Persistent diarrhea lasting between 2 and 4 weeks
- Chronic diarrhea lasting longer than 4 weeks

Diarrhea (from Greek: *diarrhoia* = *dia* = through, *rheo* = flow) is defined by the sudden excretion of fluid feces for at least more than 3 times per day. Under clinical conditions, the

Diarrhea, Table 1 Alphabetical list of pathogens that may induce diarrheas (selection)

Agent of disease genus/species	Characteristics and systematical position of the pathogen
<i>Arcobacter butzleri</i> , etc.	Gram-negative, spirillic bacteria; Campylobacteriaceae.
<i>Balantidium coli</i>	Parasite: Protozoa, Ciliate.
<i>Blastocystis hominis</i>	Parasite: Globular protozoa or fungi with varying size of 5–200 µm in diameter.
Calicivirus	See Norwalk virus: small RNA viruses of 26–35 nm in size without capsules, icosahedral, cup-like shape
<i>Campylobacter jejuni</i> and other	Gram-negative spirillic bacteria; Campylobacteriaceae, Protobacteria.
<i>Citrobacter freundii</i>	Gram-negative, rod-like bacteria with endotoxins; Enterobacteriaceae.
<i>Clostridium perfringens</i> , etc.	Gram-positive, anaerobic, short rod-like bacteria (with subterminal spore); Bacillaceae.
Coxsackievirus	Human enterovirus; Picornaviridae; spherical, not covered RNA virus of 30 nm in diameter.
<i>Cryptosporidium</i> species	Parasites: Protozoa; spherical oocysts with 5 µm in diameter.
<i>Cyclospora cayetanensis</i>	Parasite: Protozoa; Apicomplexa; oocysts with two sporozoites each with two sporozoites.
Cytomegalovirus(HCMV)	Human herpes virus linear, double-strand DNA virus with capsid; Herpesviridae.
<i>Dicrocoelium dendriticum</i>	Parasite: trematode lives in bile ducts, up to 15 mm in length.
<i>Dientamoeba fragilis</i>	Parasite: amoeba-like protozoan of up to 12 µm may form cysts.
<i>Echovirus</i> , <i>Parechovirus</i>	Human enterovirus, spherical RNA virus of 30 nm in diameter, without cover.
<i>Entamoeba histolytica</i>	Parasite: Amoeba: Minuta- (10–20 µm) and Magna-form (40 µm). The latter may enter intestinal wall and liver forming abscesses.
<i>Enterobacter sakazakii</i> , <i>E. aerogenes</i> , etc.	Gram-negative rod-like bacteria of up to 3 µm in length, formation of capsules and endotoxin; Enterobacteriaceae.
<i>Escherichia coli</i> and its variations (EHEC, ETEC, EIEC, EPEC, AEEC)	Gram-negative, rod-like bacteria of 1.5 × 2–6 µm in size, with or without capsules. EPEC, etc., are obligate pathogens; Enterobacteriaceae.
<i>Giardia lamblia</i> (syn. <i>duodenalis</i>) and other assemblages (A – G)	Parasites: flagellated protozoan (with 8 flagella as trophozoite; cyst with 4 nuclei); size 10–20 µm.
Hantavirus (<i>Hantaan</i> virus, etc.)	Virus with a minus single-strand RNA genome with a diameter of 100 nm containing three separate nucleocapsids.
Hepatitis-A-virus (HAV)	Picornaviridae virus of 27 nm in diameter without cover containing a single-strand linear+, RNA genome of about 7.5 Kb in length.
Hookworms(genera <i>Ancylostoma</i> , <i>Necator</i>)	Parasites: nematode worms of about 1–1.5 cm in length, suck blood in both sexes at the intestinal wall.
<i>Hymenolepis nana</i> , etc.	Parasite: Tapeworms of 5–6 cm in length, self-infections possible = mass infection.
<i>Isospora belli</i> (syn. <i>hominis</i>)	Parasite: Protozoan: Apicomplexa; forms oocysts of 20–30 µm × 10–20 µm containing two sporozoites each with four sporozoites.
Liver flukes (<i>Opisthorchis</i> , <i>Clonorchis</i>)	Parasites: Adult trematode worms of about 1.5 cm in length live in the bile ducts; infection by oral uptake of infected fish.
<i>Legionella</i> species	Gamma protobacteria; gram-negative, facultatively intracellular, not spore forming, short coccoid rod-like bacteria of 0.3–0.9 µm × 1.5–2 µm in size.
<i>Leishmania donovani</i> , etc.	Parasite: singly flagellated (short, hidden flagellum) protozoan that reproduces in humans intracellularly; transmitted by bites of sandflies.
<i>Listeria monocytogenes</i> , <i>L. ivanovii</i>	Gram-positive, mobile bacteria, not spore forming rod-like short bacteria with facultative intracellular reproduction; Lactobacillidae.
Measles virus, <i>Morbillivirus</i>	Virion has a size of 110–250 nm and has a cover surrounding the helical nucleocapsid with a RNA genome; Paramyxoviridae.

Diarrhea, Table 1 (continued)

Agent of disease genus/species	Characteristics and systematical position of the pathogen
Microsporidia (e.g., <i>Encephalitozoon cuniculi</i> , <i>Enterocytozoon bieneusi</i>)	Parasites small-sized, intracellular protozoans (2.5 µm), form cysts in immune-suppressed persons; generalization as opportunistic agents.
<i>Neisseria meningitidis</i>	Gram-negative, diplococci, nonmotile, nonspore forming, aerobic β-proteobacteria of 1 µm in diameter.
Norwalk-(Noro)virus (NV)	Noncovered, 27 nm sized, icosahedral virus of 27 nm in diameter containing a RNA genome, Caliciviridae.
<i>Plesiomonas</i> sp. (syn. <i>P. shigelloides</i> , <i>Aeromonas shigelloides</i>)	Motile gram-negative, rod-like bacteria with flagella at one of the two cell poles, Enterobacteriaceae.
Rotavirus (six human serotypes; two groups)	Virus of the family Reoviridae with a diameter of about 70 nm containing 11 segments of double-strand RNA.
<i>Salmonella enterica</i> , etc.	Bacteria of the family Enterobacteriaceae; gram-negative, capsule-less, nonspore forming, rod-like bacteria with a size of 1.3–4 × 2–6 µm.
<i>Sarcocystis</i> species (<i>S. suis</i> , <i>S. bovis</i>)	Parasites: Protozoa, Apicomplexa. Humans excrete oocysts with two sporocysts and each with four sporozoites or single sporocysts (after disruption of oocyst wall).
<i>Shigella dysenteriae</i>	Bacteria of the family Enterobacteriaceae; gram-negative, aerobic, rod-like bacteria without spore formation with a size of 2–6 µm × 1.3 µm; they invade intestinal cells; <i>E. dysenteriae</i> produces Shigatoxin; some authors consider <i>Shigella</i> as <i>E. coli</i> pathovars.
<i>Staphylococcus aureus</i>	Bacteria of the new classified family Micrococcaceae; stages are gram-positive coccoid bacteria, which often form clusters during growth.
<i>Strongyloides stercoralis</i>	Parasite: nematode worm, which lives as parthenogenic, 2-mm-long females in human intestine and as bisexual generation outside of the body (reaching lengths of 0.8–1 mm).
<i>Taenia</i> species (e.g., <i>T. solium</i> , <i>T. saginata</i>)	Parasites: tapeworms, reaching lengths of up to 8 m in human intestine; mostly only one adult worm per person.
<i>Trichinella spiralis</i> and related species	Parasites: nematode worms: ♀, ♂ of ~ 1–3 mm live in human intestine; (100 µm long, larvae live intracellularly in human muscle cells).
<i>Trichuris trichiura</i>	Parasite: nematode worms of 5–6 cm in length, live in the colon of humans; their thin anterior end penetrates into the interior of intestinal cells.
<i>Vibrio cholerae</i> , etc.	Bacteria belonging to the family Vibrionaceae; stages are 0.5–0.8 µm × 1.4–2.6 µm sized vibrios with comma-appearance and gram-negative reaction, polar flagella.
<i>Yersinia enterocolitica</i> , etc.	Proteobacteria (Fam. Enterobacteriaceae), short rod-like, gram-negative bacteria.

Diarrhea, Table 2 Pathogens inducing an inflammatory diarrhea (selection)

Species	Incubation period	Persistence of symptoms	Fever > 38.5 °C
<i>Campylobacter</i> species	6–48 h	~7 d	+
<i>Entamoeba histolytica</i>	2–3 m	Diarrhea: 6–14 d Abscess: months	+
Enteric <i>Salmonella</i> species	6–48 h	1–10 w	+
Enterohaemorrhagic <i>Escherichia coli</i> (EHEC, etc.)	1–8 d	3–7 d	+
Typhic <i>Salmonella</i> species	1–3 w	~4 w	+
<i>Vibrio parahaemolyticus</i>	5–1 d	~7–10 d	+
<i>Yersinia</i> species	10–48 h	1–3 w	+

> higher, more than, + yes, ~ about, *d* days, *h* hours, *m* months, *w* weeks

Diarrhea, Table 3 Pathogens inducing a noninflammatory diarrhea (selection)

Species	Incubation period	Persistence of symptoms	Fever > 38.5 °C
<i>Blastocystis hominis</i>	2–3 d–3 w	~5 w	+
<i>Clostridium perfringens</i>	14–24 h	~24 h	+
<i>Cryptosporidium</i> species	1–2 d	3–12 d	–
<i>Cyclospora cayetanensis</i>	2–7 d	2–12 w	–
Enterotoxigenic <i>Escherichia coli</i> (ETEC)	16–72 h	~10 d	+
<i>Giardia lamblia</i>	~1–2 w	~ months	–
<i>Isospora belli</i>	2–13 d	2–4 w–1 year	–
Norwalk Virus	1–2 d	1–2 d	+
Rotavirus	1–3 d	6–8 d	+
<i>Sarcocystis suis</i>	4–6 h	~24–48 h	–
<i>Vibrio cholerae</i>	1–3 d	6–9 d	–

+ present, – not present, ~ about, *d* days, *h* hours, *w* weeks

Diarrhea, Table 4 Officially obligatory registered cases of infectious diarrheas at the German Health Authorities (Robert Koch Institute, Berlin) in the year 2012

Disease due to infection with agents of disease, e.g.,	Type of agent of disease	Cases registered in 2012
Norovirus	V	112,364
Rotavirus	V	39,056
<i>Campylobacter</i> species	B	62,626
<i>Salmonella</i> species	B	20,699
<i>Escherichia coli</i> (EPEC)	B	7,027
<i>E. coli</i> (EHEC) without HUS	B	1,529
<i>Yersinia</i> species	B	2,687
<i>Shigella</i> species	B	524
<i>Giardia duodenalis</i>	P	4,326
<i>Cryptosporidium</i> species	P	1,379

B bacteria, P parasites, V viruses, *EHEC* enterohaemorrhagic *E. coli*, *EPEC* enteropathogenic *E. coli*, *HUS* hemolytic-uremic syndrome (*E. coli* with Shiga toxin)

diarrheas are divided in general into acute and chronic diarrheas.

Acute Diarrhea

This type of diarrhea is per definition always based on an infection with an agent of disease: viruses, bacteria, and parasites. The infectious diarrheas belong to the most common human infections worldwide. Table 4 shows as an example the registered cases of the German Health Authorities (Robert Koch Institute, Berlin) in the year 2012. There was registered an extremely broad spectrum of severe cases (mild ones had surely not been announced). With respect to parasites, mainly cases of infections with ► *Giardia duodenalis* and ► *Cryptosporidium* were noted.

Table 4 shows that in countries with mild climates infections with bacteria and viruses are predominant and infections with parasites are only not registered in low numbers. They exist, but are often not diagnosed or are diagnosed and treated by a broad spectrum of available antiparasitic medicaments. Main symptoms of those viral, bacterial, and parasitic acute diarrheas, which occur after short incubation periods ranging between a few hours up to 2 days and which only in a few species are accompanied by fever. Also the duration of these diarrheic symptoms (especially in bacterial infections) is rather short (1–7 days, mostly, however, only 1–2 days, if treated adequately). The treatment of bacteriosis is done in general by the use of antibiotics, but in

virus and in cases of some bacteriosis (e.g., cholera) only symptoms can be treated (e.g., water loss). Parasite infections (except for *Cryptosporidium* species) can be treated by worldwide available medicaments.

Chronicle Diarrhea

Persistent and chronic diarrheas due to parasites have to be differentiated from similar symptoms due to gastrointestinal cancer, enteropathies, sprue, colitis, lactosis- and fructosis-intolerances, diabetes, thyroidea dysfunctions, disturbances of resorption, radiogenic colitis, etc. Common cases of persistent or chronic diarrheas are known to occur during infections with

- Cytomegaly viruses
- ► *Giardia lamblia*
- ► *Entamoeba histolytica*
- ► *Cryptosporidium parvum*
- ► *Microsporidiosis* due to ► *Enterozoon bieneusi* and *Encephalitozoon intestinalis* (in cases of immune-suppressed persons)
- ► *Isospora* (syn. *Cystoisospora*) *belli*
- ► *Cyclospora cayetanensis*

Immunosuppression has to be considered during diagnosis of chronic diarrhea. In all parasites except for *Cryptosporidium* species, potent medicaments are available. However, the needed dosages and the duration of application must be strictly considered.

Diarthrophallus quercus

Prostigmata mite species found on beetles.

Diazinon (Dimpylate)

Chemical Class

Organophosphorous compounds
 (monothiophosphate).

Mode of Action

Acetylcholine esterase inhibitor. ► [Ectoparasitocides: Agonists and Antagonists of Cholinergic Transmission](#), ► [Arthropodicidal Drugs](#).

Dichelyne minutus

Nematode species in the intestine of the round goby (*Neogobius melanostomus*) in the Baltic and Black Sea.

Dichlorvos (DDVP)

Chemical Class

Organophosphorous compounds
 (organophosphate).

Mode of Action

Acetylcholine esterase inhibitor. ► [Ectoparasitocides: Agonists and Antagonists of Cholinergic Transmission](#), ► [Arthropodicidal Drugs](#).

Dicranotaenia

Genus of tapeworms of the family ► [Hymenolepidae](#). *D. coronula* lives in the small intestine of ducks.

Dicrocoeliasis, Man

Disease due to infections with the digenetic trematode ► *Dicrocoelium dendriticum* by oral uptake of infected ants being attached, e.g., to salad.

Main Clinical Symptoms

► Abdominal pain, liver enlargement.

Incubation Period

2–4 weeks.

Prepatent Period

7–8 weeks.

Patent Period

Years.

Diagnosis

Microscopic determination of eggs in fecal samples (Fig. 1).

Dicrocoeliasis, Man, Fig. 1 Egg of *Dicrocoelium dendriticum*

Prophylaxis

Clean thoroughly salad, plants, etc., from attached ants.

Therapy

Treatment see ► Trematodocidal Drugs.

Dicrocoelium dendriticum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *dikroos* = twofold branching; *koila* = body cavity; Latin: *dendriticus* = branching; English: lancet liver fluke, small liver fluke.

Geographic Distribution/Epidemiology

Worldwide in regions with chalk-rich soils; high numbers of infected animals occur in North Africa, Siberia, South America; only a few humans are infected (mostly children) due to the peculiar infection route via ants.

Morphology/Life Cycle

The small liver fluke (Figs. 1, 2, and 3) reaches a size of $5\text{--}12 \times 1\text{--}2$ mm and is highly stretchable. The blind ending intestine is bifurcated without lateral branches. The pair of lobulated testes is placed just behind the ventral sucker, and the coiled uterus fills up the posterior half of the body. The hermaphroditic adult worms live in the bile ducts of their hosts (ruminants, humans, dogs, etc.). First intermediate hosts are land snails that belong to the genera *Zebrina*, *Helicella*,

Dicrocoelium dendriticum, Fig. 1 Diagrammatic representation of the life cycles of *Dicrocoelium dendriticum* (a) and *Paramphistomum cervi* (b). Life cycles of the “flukes” *Dicrocoelium dendriticum* (a) and (*Paramphistomum cervi*) (b) in sheep and cattle (final hosts: “Digenea”/Table 1) 1 Adult worms in the bile ducts (a) or rumen (b). 2 Eggs are excreted in feces

fully embryonated (a) or not (b). 2.1 In *P. cervi* the finally formed “miracidium” hatches from the egg and enters a water snail, whereas in *D. dendriticum* land-living snails swallow the eggs containing the miracidium. 3–4 Intermediate hosts for *P. cervi* are water snails of the genera *Bulinus*, *Planorbis*, *Stagnicola*, and *Anisus*, whereas in *D. dendriticum* land snails of the genera *Zebrina* or

which ingest eggs containing the infectious miracidium larva (Fig. 1). These snails produce slime balls within which cercariae become included after being produced in sporocysts. Second intermediate hosts are ants, which ingest the slime balls with the cercariae. After ingestion, one or two cercariae penetrate into the “brain” of the ant, while others enter the stomach and are transformed there to metacercariae. The parasitizing of the “brain ganglia” leads to a changing of the ant’s behavior. Instead entering the ant stock in the evening hours, the infected ants stay outside on plants and are fixed there by a cramp of their mandibles (= mouthparts). This cramp is released in the morning hours. Since sheep feed in the early morning hours, they ingest these infected ants. In general, there are found many metacercariae in a single ant, so that the infection of a sheep starts already with several worms wandering into the liver of the new host. Very often, metacercariae use directly the ductus choledochus in order to reach the tiny bile ducts, where they grow up to reach maturity.

Symptoms of Disease (Dicrocoeliasis)

Low-graded infections show mostly no clinical symptoms. However, reduced growth and/or reduced gain of bodyweight may occur later due

to reduced bile production. Heavy infections may introduce liver cirrhosis.

Diagnosis

Microscopical demonstration of the dark brown, tiny eggs, which reach a size of $40 \times 25 \mu\text{m}$ and contain already a miracidium when deponed (Fig. 4). The eggs are only found after use of concentration methods such as “► S.A.F.C.” or “► M.I.F.C.” **Attention:** If human feces contain *Dicrocoelium* eggs, this must not be due to an existing infection but can also occur when humans have eaten liver of infected cattle.

Infection

Oral uptake of portions of infected ants (e.g., hidden in salad or attached on other plants)

Prophylaxis

Very difficult, since ants are free-living animals, which can be ingested everywhere by grassing animals. Humans should wash salad intensively.

***Dicrocoelium dendriticum*, Fig. 1** (continued) Helicella are involved. Development in snails proceeds via two generations of sporocysts in *D. dendriticum*, whereas in *P. cervi* a “► sporocyst” and 2 “► rediae” occur. Finally, tailed “► cercariae” are produced, which leave the snail 3 or are excreted by the snails within slime-balls 4.1, but remain immotile 4.2. 5-6 In *D. dendriticum* ants become second intermediate hosts when feeding slime-balls. Most of the cercariae encyst in the hemocoel 6 as “metacercariae” and can then infect the final host. 1 or 2 cercariae enter the subesophageal ganglion, encyst there, and cause an alteration of the ant’s behaviour. When the temperature drops in the evening hours, the infected ants climb to the tips of grass (and other plants) and grasp them firmly with their mandibles, while uninfected ants return to their nests (stocks). The infected

ants remain attached until the next morning, when they warm up, and resume normal behaviour. These attached ants may be swallowed by plant-eating mammals. In *P. cervi* the free-swimming cercariae (with two eye spots) encyst on herbage and other objects 6, thus becoming metacercariae. Upon being swallowed along with forage, encystment of the metacercariae of both species occurs in the duodenum. From there they enter the bile duct (*D. dendriticum*) or return (via the intestinal wall) into the abomasum (*P. cervi*), and from there go to the rumen, where they attach among the villi. *EY* eye spot, *EX* excretory bladder, *GB* “germ balls,” *GP* genital pore, *HD* head, *IN* intestine, *MC* metacercaria, *MI* miracidium, *OP* “► operculum,” *OS* oral sucker, *OV* ovary, *TA* tail, *TE* “► testis,” *UT* uterus, *VI* “► vitellarium,” *VS* ventral sucker

Dicrocoelium dendriticum, Fig. 2 Light micrograph of a stained adult worm of *Dicrocoelium dendriticum*

Dicrocoelium dendriticum, Fig. 3 Scanning electron micrograph of the anterior end of an adult worm of *D. dendriticum*. Note the oral and ventral sucker and the infolded groove with the (here not visible) openings of the uterus and the male system. The outer surface of the worm (tegument) does not contain scales (like *Fasciola* worms) and thus appears smooth

D

Incubation Period

Weeks until 3 months

Prepatent Period

Seven to eight weeks

Patency

Years

Therapy

Animals: In severe cases, the following anthelmintics showed significant efficacy:

1. **Tiabendazole:** oral 250 mg/kg bodyweight; no waiting time
2. **Albendazole:** oral 10–15 mg/kg bodyweight
3. **Mebendazole:** oral 15–20 mg/kg bodyweight
4. **Fenbendazole:** oral 50 mg/kg bodyweight

Humans: Praziquantel (see “► *Clonorchis sinensis*”)

***Dicrocoelium dendriticum*, Fig. 4** Table showing micrographs of eggs of cestodes and trematodes such as →*Dicrocoelium dendriticum* (g) and for comparison a mite

egg, which is also often in feces. D = cover (operculum); DZ = yolk cell; KB = germ ball; LA = larva; MIC = miracidium larva; ON = oncosphaera

Dicrocoelium Species in Camels

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Camels are often infected by the following trematodes: *Dicrocoelium chinensis*, *D. dendriticum*, and *D. hospes*.

Dicrocoelium hospes

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *dikros* = twofold; *koilos* = empty cavern.
Latin: *hospes* = host.

This species with a life cycle similar to that of *D. dendriticum* is found in countries south of the Sahara in Africa. It reaches a size of 4.8–7 μm $\times$ 0.8 mm. Its final hosts are cattle, goats, sheep, buffaloes, pigs, rabbits, and rarely **humans** (besides wild animals). Land snails serve as first intermediate hosts (e.g., *Limnicola* sp.). As second intermediate hosts have been described ants of the genera *Camponotus*, *Crematogaster*, and *Dorylus*.

Dicrotophos

Chemical Class

Organophosphorous compounds
(organophosphate).

Mode of Action

Acetylcholine esterase inhibitor. ► [Ectoparasitocides: Agonists and Antagonists of Cholinergic Transmission](#).

Dictyocaulus arnfieldi

Species of ► [nematodes](#). ► [Respiratory System Diseases, Horses, Swine, Carnivores](#).

Dictyocaulus Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *diktyon* = net; *kaulos* = stick. Latin:
viviparus = born in a motile stage; living born;
capreolus = deer.

Geographic Distribution/Epidemiology

These so-called large lungworms are worldwide distributed and may induce epidemics among crowded farm ruminants. Prevalence rates of 40 % are often reached in some herds.

Morphology/Life Cycle

The species of the large lungworms of the genus *Dictyocaulus* are shown in Table 1.

Dictyocaulus Species, Table 1

Species/size (mm)	Hosts	Characteristics
<i>D. arnfieldi</i> ♀ 43–60; ♂ 26–43	Donkeys, horses	Larva 1: tail with thornlike tip
<i>D. capreolus</i> ♀ 34–80; ♂ 30–60	Deer, elk	Larva 1: still unknown
<i>D. eckerti</i> ♀ 34–63; ♂ 30–47	Deer, stag, reindeer, caribou	Larva 1: tail pointed
<i>D. filaria</i> ♀ 50–100; ♂ 50–80	Sheep, goat, wild relatives	Larva 1: tail rounded
<i>D. viviparus</i> ♀ 50–70; ♂ 35–43	Cattle, wild relatives	Larva: tail pointed

The life of the *Dictyocaulus* species is depicted in Fig. 1 of the entry “► Lung Worms” of cattle. It is clearly different from the life cycles of the small strongylids. The morphology can be seen there in Fig. 2.

Symptoms of Disease

The most severe symptoms occur in juvenile hosts, if they are first time infected. Morbidity depends on the intensity of infection. During the wandering phase of the larvae, the following symptoms occur: coughing, hemorrhages, necrosis of walls of the alveolus, bronchitis, bronchiolitis, and eventually death. During patent infections, pneumonia is common as well as coughing, loss of weight, and death.

Diagnosis

Microscopical demonstration of the typically unsheathed larvae after isolation from feces by help of the Baermann technique (Fig. 3, “► Lung Worms” of animals). There occur the following larval sizes:

- *D. arnfieldi*: 420–480 µm
- *D. eckerti*: 300–360 µm
- *D. filaria*: 490–520 µm
- *D. viviparus*: 310–360 µm

Infection

Oral uptake of larvae 3 being attached on plants.

Prophylaxis

- In stables: Regular removal of straw.
- On meadows: Regular change of pastures.
- Vaccination: Use of attenuated larvae.

- Chemoprophylaxis: Application of chemotherapeutics starting about 4–6 weeks after animals started grazing.

Incubation Period

In case of first infections: in spring 5–7 days; in autumn mostly in next spring, since ► [hypobiosis](#) occurs.

Prepatent Period

Species specific 21–30 days or even up to 14 weeks in *D. arnfieldi*.

Patency

About 2–3 months (rarely up to 6 months).

Therapy

Macrocyclic lactones (e.g., **ivermectin** (1×0.2 mg/kg bodyweight), **moxidectin** (1×0.4 mg/kg bodyweight), or **fenbendazole** ($5 \text{ days} \times 1 \times 2\text{--}10$ g/kg bodyweight)) are effective.

Genus of the trematode family
► [Didymozoonidae](#) parasitizing marine fishes.

Didymozoonidae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Curiously shaped family of digenetic trematodes the members of which live in pairs in cysts on the surface, gills, operculum, or on the walls of the oral cavity or pharynx of marine fishes, seldom in the interior. Characteristics of the family are the demarcation of a slender or spoon-like forebody from the cylindroid, plump or rounded hindbody, and the slender, long, tubular shape of the ovary, testis, and yolk gland. Species of *Nematobothrium* are up to 1 m long. *Didymozoon* species possess a plump and cylindroid hindbody, while *Didymocystis* sp. has a short protruding forebody. All these genera are hermaphroditic. In contrast to this, *Wedlia* sp. is characterized by its body shape. The small male hindbody is lodged in a depression of the large rounded female hindbody, from which the tiny female forebody protrudes. Thus, these specimens are dioecious.

Dientamoeba fragilis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *di* = double, twofold; *entos* = inside; *amoibe* = changing shape; Latin: *fragilis* = fragile.

***Dientamoeba fragilis*, Fig. 1** Diagrammatic representation of a two-nucleated trophozoite

Geographic Distributions/Epidemiology

Worldwide distributed. Prevalence rates between 0.4 % and 42 % have been reported in several worldwide investigations (e.g. 9.4 % USA; 16 % British Isles).

Morphology/Life Cycle

The amoeboid trophozoites of *D. fragilis* live in the intestinal tractus (mainly colon) of humans and primates, reach a size of 3–12 μm and contain often two nuclei (Fig. 1). This is apparently the stage prior to division. The nuclei contain of condensations. In feces and in the terminal regions often 10 μm sized, thin-walled, spherical cysts occur (Fig. 2). At the beginning of their discovery history *Dientamoeba* was classified as a non-pathogenic commensal. However, the recent molecular biological studies showed that they are closely related to *Trichomonas* species and that they have a considerable pathogenic potential.

***Dientamoeba fragilis*, Fig. 2** Diagrammatic representation of a thin-walled cyst stage

Symptoms of Disease

Most infections with *D. fragilis* remain symptomless or are as low graded that an infection is not diagnosed. However, proven cases (at least in children below 10 years and in adults between 40 and 60 years) may show diarrheas, loose stools, and abdominal pain. Investigations of the members of these groups showed that these symptoms often persisted and led to chronic prolonged diarrheas or even to an irritable bowel syndrome (IBS).

Diagnosis

Microscopical demonstration proves stages in the feces after the use of concentration or culture methods. When using molecular biological methods, real-time PCR (RT-PCR) was the most sensitive method. Shedding of cysts or trophozoites occurs with intermittent phases.

Infection

Probably by oral uptake of the smooth-walled spherical cyst stages within fecally contaminated food or drinking water.

Prophylaxis

Avoiding of contact to human or primate feces. Protection of food from contact with flies which are known to transport agents of disease from stool/feces to human food.

Incubation Period

Unknown, since symptoms of disease occur often late, if at all.

Prepatent Period

Days up to weeks.

Patency

Apparently weeks to months in chronic infections.

Therapy

Metronidazol (same dose as in ► [Entamoebiasis](#)), doxycycline (2×100 mg daily for 10 days), paromomycine (3×500 mg daily, orally for 5–7 days), or iodoquinol (3×650 mg daily for 3 weeks).

Synergist.

Mode of Action

Glutathion-S-transferase inhibitor.

Diethylcarbamazine

Drug to control the larvae, i.e., the microfilariae of filariae. Nematocidal Drugs.

Diethyltoluamid (DEET)

Chemical Class

Repellent.

One of the most often used insect repellents since 1945.

Differential Diagnosis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Investigation to discriminate between two or more agents of disease.

Diflubenzuron

Chemical Class

Benzoylphenyl urea.

Mode of Action

Insect growth regulator (IGR, chitin synthesis inhibitor). ► [Ectoparasiticides: Inhibitors of Arthropod Development](#).

Digenea

Flukes

Classification

Class of ► [Platyhelminthes](#).

General Information

The 6,000 species of digenetic ► [trematodes](#) are very common and widespread parasites of all classes of vertebrates and may inhabit (as adult or juvenile worms) nearly every organ of their hosts (Table 1). Externally, they are characterized by a sucker around the mouth and an additional ventral sucker or ► [acetabulum](#) that is involved both in the attachment to host surfaces and in locomotion. The shape and location of these suckers is species specific. Digenetic development

occurs in at least two different hosts and involves several generations. The basic life cycle pattern employed by digeneans and examples of their larval stages are displayed diagrammatically in Figs. 1, 2, 3, 4, and 5.

System

The proposed classification of the class Digenea according to the origin of the protonephridial excretory system (► [Cyrtoocyte](#), ► [Platyhelminthes](#), Fig. 24) is, in outline (excluding several families), as follows:

- Class: Digenea.
- Superorder: Anepitheliocystidia (in the adult worms the wall of the larval excretory bladder is retained).
- Order: Strigeatida (► [cercariae](#) fork-tailed; miracidia with two pairs of protonephridia).
- Families: Diplostomatidae, Schistosomatidae, Spirorchidae, Bucephalidae, Strigeidae, Cyclocoelidae.
- Order: Echinostomatida (cercariae with simple tail, miracidia with a single pair of protonephridia).
- Families: Echinostomatidae, Fasciolidae, Gastrodiscidae, Paramphistomatidae.
- Superorder: Epitheliocystidia (excretory bladder is newly formed by mesodermal cells; tail of cercariae unforked).
- Order: Plagiorchiida (eggs operculated: oral stylet usually present in oral sucker of cercariae; tail of cercariae often lacks excretory vessels).
- Families: Dicrocoeliidae, Plagiorchiidae, Prosthogonimidae, Troglotremitidae.
- Order: Opisthorchiida (eggs operculated; cercariae lack anoral stylet; tail of cercariae always contains excretory vessels).
- Families: Opisthorchiidae, Heterophyidae.

Important Species

See Table 1.

Digenea, Table 1 Important families and species of digenean trematodes

Family/species	Final host/habitat	Size of adults (mm)	Size of eggs (μm)	First intermediate host ^a	Second intermediate host ^b	Prepatent period (weeks)
Allocreadiidae						
<i>Crepidostomum cooperi</i>	Fish/pyloric ceca	1.5	45 $\times$ 60	Fingernail clams	Naiads of dragonflies	3–4
Clinostomatidae						
<i>Clinostomum complanatum</i>	Herons/mouth	3–8	70 $\times$ 120	<i>Helisoma</i> spp.	Fish	3 days
Dicrocoeliidae						
<i>Dicrocoelium dendriticum</i>	Ruminants, horses, pigs, rabbits, humans/bile ducts	6–10	25 $\times$ 40	<i>Helicella</i> spp., <i>Zebrina</i> spp.	Ants	6–10
Diplodiscidae						
<i>Megalodiscus temperatus</i>	Frogs/rectum	6		<i>Helisoma</i> spp.	–	4
Diplostomatidae						
<i>Alaria canis</i>	Dog, foxes/small intestine	3–4	70 $\times$ 130	<i>Helisoma</i> spp.	Tadpoles ^c	5
Echinostomatidae						
<i>Echinoparyphium recurvatum</i>	Water birds/small intestine	5	80 $\times$ 100	<i>Helisoma</i> spp.	Snails, tadpoles	2
<i>Echinostoma ilocanum</i> , <i>E. echinatum</i>	Humans , dogs/small intestine	2.5–6.5	65 $\times$ 95	<i>Gyraulus</i> spp.	Snails, clams	3
<i>E. revolutum</i>	Birds/rectum, cecum	10–22	65 $\times$ 110	<i>Helisoma</i> spp., <i>Physa</i> spp.	Tadpoles, snails	3
<i>Himasthla</i> sp.	Humans , gulls/small intestine	11–17	70 $\times$ 130	<i>Nassa</i> spp.	Clams	2
Fasciolidae						
<i>Fasciola hepatica</i>	Sheep, cattle, horses, humans /bile ducts	20–30	70 $\times$ 140	<i>Lymnaea</i> spp.	Water plants	8–13
<i>Fasciolopsis buski</i>	Humans , pigs/small intestine	30–75	80 $\times$ 135	<i>Gyraulus</i> spp., <i>Planorbis</i> spp.	Water plants + fruits	9–13
<i>F. gigantica</i>	Cattle, horses/bile ducts	25–75	90 $\times$ 140	<i>Lymnaea</i> spp.	Water plants	9–13
Heterophyidae						
<i>Heterophyes heterophyes</i>	Humans , fish-eating mammals/small intestine	1–2	14 $\times$ 24	<i>Pirenella conica</i>	Marine fish	1–2
<i>Metagonimus yokogawai</i>	Humans , fish-eating mammals/small intestine	1–2	16 $\times$ 28	<i>Semisulcospira</i> spp.	Freshwater fish	1–2
Opisthorchiidae						
<i>Metorchis conjunctus</i>	Dogs, cats, humans /gallbladder	1–6.5	15 $\times$ 25	<i>Amnicola</i> spp.	Fish (<i>Catostomus</i>)	4–5

m male, f female

^aSeveral other species of gastropods may become first intermediate host

^bThere is no reproduction either in the true second intermediate hosts or on water plants

^cHere so-called mesocercariae are found; third intermediate hosts are snakes or rats which contain metacercariae

Life Cycle

Except for some groups (e.g., the ► **dioecious** Schistosomatidae; Table 1), flukes are hermaphroditic, utilizing sexual reproduction (with cross-insemination) in the final host. The tanned eggs are produced after fertilization inside a complex system consisting of a central ► **ootype** (► **Oogenotop**), an ovary, vitelline glands, Mehli's glands, and uterus (Figs. 6 and 7). These eggs leave the host through feces, urine, or sputum, and the ► **zygote** within the eggs develops (or has already developed by this stage) into a ciliated larva (► **Miracidium**; Fig. 2) In general, this stage infects a gastropod mollusk or a lamellibranch (by penetration or via oral

uptake = *Clonorchis*) as first intermediate host, inside which a polyembryonic, mitotic reproduction occurs involving different developmental stages (► **Sporocysts**, ► **Rediae**) and leading finally to the production of numerous motile and infective ► **cercariae** (Fig. 5). The latter leave the first intermediate host, often with a marked rhythm and, in some species, enter a second intermediate host (e.g., *Clonorchis*) or attach to the surface of plants or in others directly penetrate the final host (Table 1, Figs. 2 and 8).

Inside the second intermediate host or on the surface of plants the cercariae encyst and develop into metacercariae; cyst walls are totally or partly produced by cystogenous glands in the cercarial apex.

Digenea, Fig. 1 (a–g) Some common types of adult digenean worms, which are differential according to the appearance of their holdfast organs (e.g., suckers). The

location of sexual organs is only approximate. *HK* hooks at collar, *IN* intestine, *M* mouth, *OS* oral sucker, *OV* ovary, *PH* pharynx, *TE* testes, *TR* tribocytic organ, *VS* ventral sucker

The metacercariae grow and become mature adults when orally ingested by the final host. Inside the final host, they feed on its fluids depending on their final habitat (Table 1). Nutrients are taken up and digested by means of their anus-less, branched intestine (Figs. 3 and 4) and via the characteristic syncytial ► **tegument** (► **Platyhelminthes**, Figs. 11, 12, and 13).

Reproduction

While the formation of the digenean eggs and of the first larva (miracidium) is rather well

understood (reproductive organs), the ontogeny of other larvae remains a problem which is very complex and far from being solved. Electron microscopic studies have shown that the light microscopically visible germ balls consist of mitotically dividing cells which give rise to embryos (► **Polyembryony**?) (Fig. 9; sporocysts, rediae, or cercariae) and to a line of new germ cells that become included in these embryonic stages. Since the absence of meiotic processes is not proven, the exact definition remains doubtful. The same is true for embryonic development in the monogenean genus ► **Gyrodactylus**. In any case, however, both processes are successful

Digenea, Fig. 2 Some common pathways of digenean life cycles. (1) Egg-miracidium-redia-cercaria-metacercaria-adult worm (e.g., *Caecinola* sp.). (2) Egg-miracidium-redia I-redia II-cercaria-metacercaria-adult worm (e.g., *Stichorchis* sp.). (3) Egg-miracidium-sporocyst-redia-cercaria-metacercaria-adult worm (e.g., *Metorchis* sp.). (4) Egg-miracidium-sporocyst I-redia I-redia II-cercaria-metacercaria-adult worm (e.g., *Fasciola hepatica*, *Clonorchis sinensis*).

(5) Egg-miracidium-sporocyst-cercaria-metacercaria-adult worm (e.g., Bucephaloidea species). (6) Egg-miracidium-sporocyst I-sporocyst II-cercaria-metacercaria-adult worm (e.g., *Dicrocoelium dendriticum*, *Prosthogonimus* sp.). (7) Egg-miracidium-sporocyst I-sporocyst II-cercaria-adult worm (e.g., *Schistosoma* sp.). (8) Egg-miracidium-sporocyst I-sporocyst II-cercaria-mesocercaria-metacercaria-adult worm (e.g., *Alaria* sp.).

means of increasing the biotic potential and producing numerous daughter organisms.

Some digenean species belonging to the superfamilies Brachylaemoidea (e.g., *Postharonostomum* spp., *Leucochloridium* spp.) and Bucephaloidea (e.g., *Bucephalus* spp.) form branching sporocysts. By constrictions such branches may split off and finally grow to their former size. This occurs by mitotic divisions of undifferentiated cells which are found below the body wall (► *Platyhelminthes*, Fig. 10).

Integument

The shape and the development of the peculiar ► *body cover* is described under ► *Platyhelminthes*/► *Integument*. In addition, it is noteworthy that all larval stages seem to have a ► *surface coat* containing proteoglycans (acid mucopolysaccharides). In the miracidium even the ► *cilia* are covered by a ► *surface coat*. Mother sporocysts of *Fasciola hepatica* and *Schistosoma mansoni* show an amplification of

Host Finding

Miracidia

Miracidia which actively reach their aquatic snail hosts are infectious for only a few hours, and their behavior seems to center entirely around finding

and invading the host snail. Their behavior patterns have functions in at least four phases of host finding:

- Dispersal. After escaping from the egg, some miracidial species tend to disperse from the site

Digenea, Fig. 5 (a–i) Some common types of cercariae.

(a) Amphistome cercaria (Ophthalmocercaria). (b) Monostome cercaria. (c) Echinostome cercaria. (d–f) ▶ *Xiphidiocercariae*. (d) Microcercous cercaria, (e) Xiphidiocercaria, (f) Cotyllocercous cercaria. (g)

Trichocercous cercaria. (h, i) Furcocercous cercariae, (h) Gasterostome cercaria, (i) Apharyngate cercaria. *EY* eyespot, *HD* head, *IN* intestine, *OS* oral sucker, *PH* pharynx, *SP* tegumental spines, *ST* stylet inside the oral sucker, *TA* tail, *VS* ventral sucker

of origin. They swim relatively fast and linearly, and even their ▶ *orientation* to light and gravity seems to be conducive to dispersal. Species which later infect ground-dwelling hosts can exhibit photopositive and geonegative orientation for approximately the first hour after emergence. During this phase, some miracidia are not as responsive and infective to their host snails as they are in later phases of the host-finding process.

- Microhabitat selection. Most miracidia tend to accumulate in the microhabitats which are

preferred by their host snails. This is achieved by responding to environmental stimuli such as light, gravity, temperature, and the magnetic field. The type of orientation may resemble very closely that of the host snail. For example, *Schistosoma mansoni* miracidia show a geonegative and photopositive orientation as do their host snails. The type of orientation may be modified by certain ▶ *environmental conditions*. For example, the negative photoresponse of ▶ *S. haematobium* miracidia reverses with decreasing temperature and they

Digenea, Fig. 6 Diagrammatic representation of the reproductive organs of a digenean trematode. *CI* ▶ *cirrus*, *CS* cirrus sac, *D* fused vitelloduct, *EG* egg, *EX* excretory bladder, *GL* glands, *GP* genital pore, *IN* intestinal branches (interrupted), *L* Laurer's canal, *MG* ▶ *Mehlis' glands*, *OS* oral sucker, *OT* ▶ *ootype*, *OV* ovary, *PH* pharynx, *RS* receptaculum seminis, *TE* testis, *UT* uterus, *VD* vas deferens, *VE* vas efferens, *VI* vitellarium, *VS* ventral sucker

were found to infect their host snails in summer preferentially at the bottom of the water and in winter near the water surface. Miracidia of ▶ *S. japonicum* reverse their photopositive orientation to a negative one with increasing temperature and/or light intensity, a behavior which also resembles that of the host snails.

The photopositive orientation of at least *S. mansoni* miracidia is a phototaxis, as the miracidia are able to detect the relative intensities of two separate sources of light. The wavelengths to which the organisms respond have been determined for miracidia of *Fasciola hepatica*, ▶ *Schistosomatium douthitti*, *S. mansoni*, and *Bunodera mediovitellata*. They all respond maximally to blue-green light between 500 and 550 nm, which penetrates deepest into clear water. *S. mansoni* and *B. mediovitellata* miracidia prefer in addition red-brown light of 650 nm, which is typical for muddy waters.

Several miracidial species are able to perform georientation independently of their photoresponses, but the mechanisms involved in this type of orientation are not well understood. A special mechanism occurs in miracidia of *Philophthalmus gralli*. Their strong geopositive orientation seems to be brought about by a sensitive north-seeking magnetotaxis in the northern hemisphere.

Digenea, Fig. 7 Diagrammatic representation of the reproductive organs of a female of *Schistosoma mansoni*. *EG* egg (containing the zygote and vitellary cells), *MG* Mehlis's glands, *O* oviduct, *OC* oocyte, *OD* ovovitellary

duct, *O* ootype, *OV* ovary, *RS* receptaculum seminis, *S* sphincter, *UT* uterus, *VC* vitellary cell, *VD* vitellary duct, *VI* vitellarium

Digenea, Fig. 8 Life cycles of four species of digenetic trematodes parasitizing different human organs, thus representing different types of development and transmission (for similar species and details see Table 1). (A) Freshly excreted eggs may or may not contain a **miracidium** (in the latter cases it develops after excretion). Egg size and shape vary with species (Table 1). (B) Except for *Clonorchis* (where the whole egg is swallowed) this miracidium hatches from the egg in water. (C) The miracidium (mother **sporocyst**) penetrates the hepatopancreas of the first intermediate host (Table 1). (D) Inside the intermediate host cercariae are formed by sporocysts (*Schistosoma*) or by **rediae** (other genera); these cercariae leave the host.

(E) The cercariae follow species-specific pathways; they may encyst on waterplants (*Fasciolopsis*), penetrate and encyst in a second intermediate host forming metacercariae (*Clonorchis*), or immediately penetrate the final host (schistosomes). (F) Encysted metacercariae need some time for development (maturation) before they can infect the final hosts. (G) The final host is infected by oral uptake of metacercariae or by cutaneous penetration of metacercariae. The worms reach maturity in the intestine (*Fasciolopsis*), bile duct (*Clonorchis*), lung (*Paragonimus*), or in blood vessels of the intestine (*Schistosoma*)

Digenea, Fig. 9 (A–D) Diagrammatic representation of the formation of daughter individuals in digenean trematodes. (A) Germinal (undifferentiated) cells are found singly inside the lumen of the mother individual (mother sporocysts, daughter sporocysts, rediae). (B) Protruding parts of the syncytial subtegumental layer surround the dividing germinal cells. (C) Now the subtegumental layer has completely surrounded the dividing cells. (D) The growing daughter organism increases in size. It is covered by a smooth primary layer, under which a new syncytial

tegument is formed by fusion of undifferentiated cells. Stages in (C) and (D) are also described as “germ balls.” BL basal lamina, CO connection between tegument and subtegumental layer, ER endoplasmic reticulum, G germinal cell, N nucleus, NU ► nucleolus, PA protonephridial anlage, PC primary cover (formed by ST), PS protruding part of subtegument, RM remnant of muscle, ST subtegumental layer, TA tegument anlage, TG tegument (differs in the different developmental stages), TH thorn (hook)

- **Host-directed orientation.** When miracidia enter the host-snail’s active space, they approach the host by responding to snail-emitted chemical signals. The type of orientation is a chemokinesis in most species studied so far, e.g., in *Schistosoma mansoni*, *S. haematobium*, *Trichobilharzia ocellata*, *Fasciola hepatica*, and *Echinostoma caproni*. The organisms increase their rate of change of direction (RCD) in increasing stimulus concentration gradients and they perform a sharp 180° turn when the concentration of the stimulus decreases (Fig. 10A, B). For this type of orientation, the miracidia must only detect an increase or a decrease of the stimulus concentration. This is possible although the miracidia rotate along their long axis, which supports a straight path of movement. However, *S. japonicum* miracidia show a directed

chemotaxis (Fig. 10C) and the rotating organisms seem to detect the direction of the concentration gradient in an unknown way.

Much research was performed using various methods to identify the attractive components of snail tissues, mucus, and snail-conditioned water (SCW). Most work dealt with miracidia of *S. mansoni*, but the results were very controversial. Small molecular compounds with low host specificity were described, such as amino acids, magnesium ions, decreasing calcium ion concentration, peptides, short-chain fatty acids, N-acetylneuraminic acid, ► ammonia, hydrogen ions, ► glutathione, and glucose. However, recent studies identified macromolecular glycoconjugates as the exclusively attracting molecules of SCW in miracidia of *S. mansoni*, *S. haematobium*, *T. ocellata*,

D

Digenea, Fig. 10 Mechanisms of chemoorientation of miracidia towards their snail hosts or snail-conditioned water and its fractions can be studied in choice chambers. The miracidia are released from the miracidia chambers by opening the closure ring (*spotted*) and their swimming paths in increasing and decreasing concentration gradients of attractants recorded. Most miracidia show an increase of

their rate of change of direction (RCD) in increasing concentration gradients of the attractants (A) and a turnback swimming in decreasing gradients (B). Only *S. japonicum* miracidia were found to be capable of a directed chemotaxis in increasing concentration gradients (C) (Modified after Haas W et al. 2002, Haberl B et al. 2000)

F. hepatica, and *E. caproni*, and there is some evidence that other species are also attracted by macromolecules. The molecules which attract *S. mansoni*, *T. ocellata*, and *F. hepatica* have very similar chemical characteristics, their saccharide chains are linked to a core protein via an *O*-glycosidic linkage probably between threonine or serine and *N*-acetylgalactosamine, and their identification signal is encoded in the carbohydrate moiety. At least the miracidia of *F. hepatica*, *T. ocellata*, and an Egyptian strain of *S. mansoni* identify their respective host-snail species with a very high specificity and sensitivity (Fig. 11). The signaling macromolecules are effective at concentrations as low as 1 mg in 10,000 l of water, and the signaling carbohydrate structures not analyzed so far may be recognized at an even considerably lower concentration.

- Host contact and invasion. After contact with solid surfaces miracidia show at least 12 different behavior patterns (MacInnis), the typical behavior at the suitable host-snail's surface is

“repeated investigation.” This response is stimulated by the same host-specific glycoconjugates which stimulate the preceding chemoorientation, at least in *S. mansoni*, *S. haematobium*, *T. ocellata*, and *F. hepatica*. The releasing cues for the subsequent attachment and penetration behavior patterns are poorly studied. At least in *S. mansoni* attachment and penetration is stimulated by the same glycoconjugates which release the preceding host-finding behaviors. This suggests that miracidia, in contrast to other parasites, use only this single complex signal for all of their host-finding phases.

A typical characteristic of digenean-snail interactions is a stringent degree of specificity. Each species of digenean is capable of developing only in very few of the available snails, often only a single species or geographic strain. The highly specific ► [host-finding](#) behavior of miracidia is obviously fully adapted to this situation. The degree of miracidial specificity in host finding

Digenea,

Fig. 11 Specificity of miracidial host finding: The miracidia of *Fasciola hepatica* and *Trichobilharzia ocellata* orientate exclusively toward the isolated signal fraction of their respective host-snail species (framed) with the responses like increase of RCD (spotted bars) and turnback swimming (hatched bars) (Fig. 10). The signal fraction (elution volume 100–150 ml) was isolated from snail-conditioned water (SCW) by molecular filtration, followed by ion-exchange chromatography, and two succeeding size exclusion chromatographies; lines indicate the protein content, and triangles the carbohydrate content of the fractions (Modified after Haas W, van de Roemer A. (1998))

may vary even within a species: An Egyptian strain of *S. mansoni* responded highly specifically only to its host-snail species, but a Brazilian strain could not differentiate between snail species. This could mean that the Brazilian parasites may have lost their original specificity as an adaptation to new intermediate host snails after they were introduced by slave transports from West Africa. The high specificity, which normally underlies miracidial host finding, may be easily overlooked in laboratory experiments, where the miracidia are exposed to the snails in a few milliliters of water. However, in the field the specific host-finding behavior might be a determining factor of the parasite-snail compatibility. First semifield studies demonstrated that a high host specificity of the host-finding behavior in miracidia greatly supports their transmission success. The fact that the

host-snails signal their species specificity with such precision despite 400 million years of ▶ [coevolution](#) with their digenean parasites suggests that the snails might need the signal molecules for other purposes. They might serve as pheromones for intraspecific communication of the snails, and the digeneans possibly just misuse them for safe host identification. Whether the attractants can be used for specific control methods still has to be investigated.

Cercariae

Cercariae of many digeneans find and recognize their hosts with complex behavior patterns and via very different, highly sensitive, and specific receptors. They have evolved an enormous diversity of host-finding strategies and can achieve very high host specificities. This indicates that

cercarial host finding plays a central role in the transmission of digeneans and that it is an important determinant in the evolution of their life cycles.

Cercariae of many digenean species invade their hosts directly within aquatic habitats. They are provided with limited accumulated energy reserves and must invade the hosts within their short life span of only 1–3 days. Most species support the transmission success by producing high numbers of cercariae (up to 500,000 cercariae per host snail daily). In addition to this, most cercariae show complex behavior patterns which seem entirely dedicated to finding hosts. The various cercarial behavior patterns have functions in the following host-finding processes:

- Departure from the snail host and dispersal. Immediately after leaving the snail hosts some species (such as ► *Diplostomum spathaceum* and *Schistosoma haematobium*) show a particularly high swimming activity which carries them away from the snails towards their preferred position within the habitats. Some cercarial species that infest snails as second intermediate hosts avoid superinfections of the first intermediate host snails that emit them with characteristic behavior. They show phases of converted orientation towards light and gravity in their immediate postshedding period, and they search their second intermediate hosts later. For example, cercariae of *Hypoderaeum conoideum* start chemotactic orientation towards snail hosts at the earliest 1 h after they have left their first intermediate host snails.
- Habitat selection. Most cercariae tend to disperse in the habitats normally frequented by their potential hosts. For example, cercariae of human schistosomes accumulate in the uppermost water layers, whereas parasites of ground-dwelling invertebrates orientate towards the bottom of waters, and some of them select microhabitats there with a defined light intensity. This habitat selection is achieved with different types of spontaneous swimming behavior and by responses to environmental stimuli, such as gravity, light and

shadow, water currents, temperature, and physical boundaries. The different species show an enormous diversity of mechanisms in responding to environmental cues. For example, some species achieve georientation exclusively by gravity-determined swimming movements, other species respond only to the direction of light radiation, and still others adjust their position in the water column by responding only to light intensity, independent of the direction of the light source.

- Localization in host time. Even the time of day the cercariae occupy the microhabitats is correlated with the habits of the subsequent hosts. This is in part achieved by the pattern of cercarial emergence from the host snail. For example, the human schistosomes leave their host snails in the middle of the day, *Schistosomatium douthitti* at night when their rodent hosts are active, and *S. margrebowiei* shows two emission peaks, one at dawn and one at dusk, i.e., when their antelope hosts water. Even an intraspecific polymorphism in the shedding patterns was found: *S. mansoni* cercariae left their snails in foci with humans as hosts mainly at 11–12 h, but in nearby foci with rats as hosts at 16–17 h. The emergence behavior is hereditary, and it is synchronized in schistosomes mainly by the photoperiod, but the thermoperiod and other factors also have an effect.
- Host-directed orientation. In many cercariae, a first contact with the host seems to occur by chance. However, some species respond to stimuli emanating from their hosts in such a way that the chances of encountering the host increase. Three types of stimulating host cues have been studied in more detail: chemical cues, water turbulence and touch, and dark stimuli (Table 2).

Chemical cues: Chemoorientation towards the host has been found in echinostome cercariae, which invade slowly moving aquatic snails (Table 2). Three species show chemokinetic orientation, they simply turn back when the concentrations of snail-emitted amino acids, urea, and ammonia decrease. However, one species can swim by being directed

Digenea, Table 2 Host cues supposed to facilitate approach of swimming cercariae toward the host; –, no effect; [], weak effect

	Chemicals	Water turbulence or touch	Dark stimuli
Schistosomatids invading mammals and birds			
<i>Schistosoma haematobium</i>	– (?)	–	Start of long swimming movements – During swimming

? = unknown

chemotactically along increasing concentration gradients of snail-emitted peptides. A prerequisite for this chemotaxis is that the cercariae can detect the direction of the

concentration gradient. Most other cercariae, which invade faster moving hosts, do not seem to use long-distance chemorientation. Only *S. mansoni* responds to skin compounds

Digenea, Fig. 12 Host finding of the duck parasite *Trichobilharzia ocellata*: Function of the cercarial responses to external stimuli (boxes) (From Haas W, van de Roemer A. (1998))

(fatty acids and arginine residues) by a reversal of the swimming direction, and this may guide them from hairs to the skin surface.

Water turbulence and touch: The schistosome cercariae respond only poorly or not at all to water currents. This may help to avoid energy-consuming responses to the frequent encounters with water-inhabiting nonhost organisms. The cercariae of the duck parasite *T. ocellata* react to water currents with forward swimming and a readiness to respond to host cues with attachment. This response is inhibited when the parasites save energy by clinging to the water surface (Fig. 12). All fish-invading cercariae of Table 2 respond to water currents by starting to swim, which may increase the chance of a contact with the moving hosts. At least in *D. spathaceum* and *horchis viverrini* water turbulence not only triggers long swimming movements but also evokes attachments, when the current-excited cercariae swim against solid substrates.

Dark stimuli: All fish parasites of Table 2 respond to shadow stimuli with the start of swimming movements. Whether this behavior may support an encounter with the fish hosts is not clear, as the shadow stimulus simultaneously inhibits the triggered swimming bursts and as it does not stimulate attachments. Among the *Schistosoma* species of Table 2 only *S. haematobium* responds significantly to shadows. The cercariae shift to a high swimming activity, which leads them upward in the water column, and this may increase the chance for an encounter with their human hosts. In the duck parasite *T. ocellata*, a shadow response plays a dominant role in host finding (Fig. 12). These cercariae prefer an energy-saving position clinging to the water surface, where they do not respond to the frequent water current stimuli. But when a shadow falls on them they swim away from its source, usually downward. This may increase the chances of encountering the feet

of their duck hosts. The shadow simultaneously triggers a readiness to respond to thermal and chemical duck foot cues with attachment behavior. Wavelengths to which cercariae respond maximally are 500 nm in *T. ocellata*, 490 nm in *S. mansoni*, and 550 nm in *Bunodera mediovitellata*.

- Host contact and invasion. After contact with the host's surface, the cercariae recognize and invade the host with a series of behavior patterns which can be carried out spontaneously or in response to host signals of quite different host specificity: (1) Attachment to the host; (2) enduring contact with (remaining on) the host; (3) creeping to suitable entry sites; (4) penetration into the skin with elements such as penetration movements, shedding of the tail, secretion of acetabular gland contents, and tegument transformation for ► [immune evasion](#). Each of these behavior patterns may be stimulated independently by separate host signals. Some species achieve a very narrow host specificity employing strategies including: (1) A chronological succession of responses to different stimuli, which themselves may be of low specificity; (2) responses to a combination of different stimuli; (3) sensitive responses to individual stimuli with a high host specificity. A typical characteristic of cercarial host finding is a high diversity of strategies. Each species studied so far recognizes its host with responses to host signals that differ considerably from those of other species, even when these invade the same host genera. This may reflect adaptations to maximal transmission successes within differing ecological conditions. The stimulating cues for cercarial behavior after host contact have been analyzed for species invading mammals, birds, and fish (Table 3).

Schistosomes invading mammalian hosts (Table 3) find their host in a characteristic manner, either by responses to different host signals or by an individual sensitivity of the responses. For example, *S. mansoni* cercariae respond in each of the host-finding phases with a particular

sensitivity to chemical host cues. It was speculated that this might represent an adaptation to clear water habitats or to an infection near the water surface, where the detection of chemical cues is not disturbed by mud components. In contrast to that, *S. haematobium* cercariae respond most sensitively to thermal stimuli. They attach maximally to substrates when their temperature exceeds ambient temperature by only 1 °C (*S. mansoni* 11–13 °C), and they migrate along temperature gradients as low as 0.03 °C/mm (*S. mansoni* 0.15 °C/mm). This specialization on thermal host cues was interpreted as adaptation to invading the hosts in cooler habitats, where warm host surfaces are especially contrasting. A very low specificity occurs in the host finding of *S. japonicum* cercariae. They attach to and remain on the host purely by chance and their penetration behavior and tegument transformation can be stimulated by warmth alone. This bears the risk of cercarial losses by penetration attempts into warm nonhost substrates. However, this behavior enables the *S. japonicum* cercariae to invade a broad spectrum of mammals including species with a low content of free fatty acids in their skin surface. Their poor response to chemical host cues was interpreted as an adaptation to the muddy habitats in which they actually invade their hosts, i.e., habitats where chemical components of mud could interfere with chemoreception.

A common characteristic of all schistosomes studied so far is that they respond very sensitively to certain free fatty acids of mammalian skin surface with penetration behavior and transformation of their tegument for immune evasion. There is evidence that the fatty acids act via chemoreceptors and neural mechanisms. However, they may also have other functions in the invasion processes. *S. mansoni* and *T. ocellata* cercariae synthesize various eicosanoids when they are incubated in essential fatty acids, and it was suggested that these might directly act in the tegument transformation and immune evasion processes.

Host recognition of bird-invading schistomatids has been studied only in three species in detail (Table 3). The host cues to

Digenea, Table 3 Host signals as stimuli for cercarial host recognition and invasion phases

	Attachment	Enduring contact	Directed creeping	Penetration
Species invading mammals				
<i>Schistosoma haematobium</i>	[L-arginine] Warmth	No stimuli?	L-arginine Temperature gradients	Fatty acids (not warmth)

Modified after Haas W, van de Roemer A. (1998)

which they respond are also characteristic for mammalian skin and this suggests that they are not adapted to avoiding unsuccessful penetrations into mammals. In fact, several bird-invading schistosomatids are known to cause ► [cercarial dermatitis](#) in humans. Each of the species studied so far responds to ceramides or cholesterol as host cues. These lipids also occur in mammalian skin surface, but they are lacking in the birds' uropygial gland secretions which are distributed on the feathers. Therefore, the response to these lipids may help to avoid useless attachments or penetration attempts to bird feathers.

Detailed data are available only for three fish-invading species (Table 3). The attachment response of *D. spathaceum* is stimulated by host-derived carbon dioxide, and the cercariae attach to nearly all animals. The disadvantage of the low specificity may be overcome by a high sensitivity to carbon dioxide, which allows a very fast attachment. The fish specificity is then achieved during the enduring contact and penetration phases, where the *D. spathaceum* cercariae respond to glycoconjugates. Each of the three fish-invading species achieves its fish specificity by responses to 1–2 types of macromolecules. How the specificity is encoded in the signaling proteins

and glycoconjugates is poorly understood. There is some evidence that terminally positioned sialic acids in the mucus are used to distinguish a host fish from mucus-covered aquatic invertebrates.

Dilepis

Genus of cestode family Dilepididae, the species of which live in birds. Related genera are ► *Dipylidium* in mammals, *Liga* in birds, *Paradilepis* in birds, *Ophiovalipora* in snakes.

Dimethoate

Chemical Class

Organophosphorous compounds (dithiophosphate).

Mode of Action

Acetylcholine esterase inhibitor. ► [Ectoparasiticides: Agonists and Antagonists of Cholinergic Transmission](#).

Dimetridazol

Drug to control infections with *Giardia*, *Trichomonas*, *Entamoeba*. ► [Antidiarrhoeal and Antitrichomoniasis Drugs](#).

Diminazen

Drug that acts against ► *Babesia* and ► *Trypanosoma* by interference with the DNA – synthesis. ► [Babesiacidal Drugs](#).

Dimpylatum

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Other name for the organophosphate ► [diazinon](#) being used as contact of food poisons against insects and other arthropods.

Dinobdella ferox

Leeches of this species enter the nasal cavities of domestic animals in Southern Asia to suck blood (► [Leeches](#)).

► [Respiratory System Diseases, Horses, Swine, Carnivores](#), ► [Respiratory System Diseases, Ruminants](#).

Dinotefuran

Chemical Class

Neonicotinoide

Mode of Action

Nicotinic acetylcholine receptor agonist. ► [Ectoparasiticides: Agonists and Antagonists of Cholinergic Transmission](#).

Dioctophyme renale

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *diktyon* = net; *phyme* = waste. Latin: *renale* = belonging to the kidney. English: Giant kidney worm.

Geographic Distributions/Epidemiology

This worm occurs in dogs, foxes, cats, wolves in Brasilia, Europe, USA, China, Japan; They are also rare in cases in humans, however, mostly in mustelids.

Morphology/Life Cycle

The adult worms (female = 100×0.8 cm; male 35×0.3 cm) appear bloody red and live mainly in the cavity of the kidney (Fig. 1). The typical eggs (Fig. 2) measure 75×50 μ m, have a thick shell, and are excreted in the 2-cell-stage. In fresh water or humid soil, the larva 1 is developed and hatched, if this egg is swallowed by the intermediate host (oligochaetes: earthworms etc.), where the larva 3 is developed within 100 days. The infection of the final hosts (dogs and rarely humans, children) occurs if they swallow infected intermediate hosts. If paratenic hosts such as fish or frogs have ingested infected intermediate hosts, they may also transmit these larvae 3 to final hosts, whereby these larvae penetrate into the body cavity and from there into the kidneys and (rarely) also into the pleural cavity.

Symptoms of Disease

Haematuria; inflammations of the kidney wall, fever.

Diagnosis

Microscopical demonstration of the typical eggs in the urine after centrifugation.

Infection

Oral uptake of infected intermediate or paratenic hosts (see above).

Prophylaxis

No feeding of raw fish to dogs or undercooked potential paratenic hosts.

Incubation Period

Two to four weeks.

Prepatent Period

Five to six months.

Dioctophyme renale, Fig. 1 Diagrammatic representation of the life cycle of *Dioctophyme renale*. The bloody-reddish adults live in the cavity of the kidneys and excrete unembryonated eggs. In fresh water the larva 1 develops inside the eggs. Annelids are the intermediate hosts,

wherein the infectious larva 3 is formed. This larva 3 can also be ingested by crustaceans or fish. If annelids or the paratenic hosts are swallowed by the final host, the life cycle is finished in its kidneys

***Diectophyme renale*,**

Fig. 2 Diagrammatic representation of the brownish-yellow eggs of *D. renale*. *Left*: surface; *right*: Inside look shows the larva 1

D

Patency

One to three years.

Therapy

Chirurgical removal of the worms from the kidneys. A registered chemotherapy is unknown, however, anthelmintics, such as ivermectin or doramectin (0.3 mg/kg bodyweight), or fenbendazole are highly effective.

Dioecious

Males and females being different individuals.

Dioecocestus

Genus of ► [tapeworms](#), the specimens of which are not hermaphrodites but form male and female adults.

Diorchis stefanskii

Tapeworm in the intestine of ducks.

Dipetalogaster**Classification**

Genus of triatomid ► [bugs](#). ► [Kissing Bugs](#).

Dipetalonema

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Genus of nematodes, which is considered as a synonym of ► [Acanthocheilonema](#) species.

Dipetalonemiasis, Man

Zoonotic dipetalonemiasis is usually an infection of porcupines, beavers, or other mammals which

is transmitted accidentally to man by ► [mosquitoes](#). The adults live subcutaneously or in body cavities of the natural host, and are found subcutaneously or in the eyes of humans. Very rarely microfilariae are found, but their specific affinities usually remain undetermined. Living worms give rise to little inflammation, but dead worms cause hypersensitivity, necrosis with eosinophils, followed by granulomatous reaction and fibrosis (compare ► [Onchocerciasis, Man](#)).

Therapy

► [Nematocidal Drugs, Man](#).

Diphylla ecaudata

Heinz Mehlhorn

Düsseldorf, Germany

Bat species from warm regions in South, Middle, and southern North America (so-called comb-teethed vampire). See ► [Blood-Licking Bats](#).

Diphyllidea

Family of cestodes with two genera: *Echinobothrium* and *Ditrachybothrium*, all parasitizing in fish (elasmobranchs).

Diphyllbothriasis, Man

Disease due to infection with the tapeworm ► [Diphyllbothrium latum](#) (► [Pseudophyllidea](#)) by oral uptake of larvae (plerocercoids) in undercooked fish.

Main Clinical Symptoms

► [Abdominal pain](#), ► [anaemia](#) due to deprivation of vitamin B₁₂.

Incubation Period

3 weeks, if symptoms occur.

Prepatent Period

21–24 days.

Patent Period

10 years.

Diagnosis

Microscopic observation of proglottids and eggs in faecal samples (Figs. 1 and 2).

Prophylaxis

Avoid eating raw fish.

Diphyllbothriasis, Man, Fig. 1 Proglottids of *Diphyllbothrium latum*, which are broader than long

Diphyllobothriasis, Man, Fig. 2 Operculated egg of *Diphyllobothrium latum* containing the coracidium larva

Therapy

Treatment with praziquantel, see ► [Cestodocidal Drugs](#).

Diphyllobothrium latum

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *di* = two, double; *phyllos* = leaf; *bothros* = deepening, slit. Latin: *latus* = broad. Thus, this name describes a worm with two slitlike suckers at the scolex. English: broad fish tapeworm of humans

Geographic Distribution/Epidemiology

This species occurs along the coast of the East Sea, in rivers of the Wolgan Valley, along the coasts of Bodensee in Germany, Switzerland, and Austria, in Italian rivers in the delta of the Danube, in Near East, Siberia, Manchuria, Japan, North America, East Asia, Australia, and in the deltas of African rivers.

Morphology/Life Cycle

The adult tapeworms reach in humans a length of up to 20 m but also occur in the intestines of fish-eating mammals such as cats and dogs or seals (Fig. 1). Up to 4,000 proglottids (they are broader than long; Fig. 2) had been counted in some worms obtained after treatment from human intestines. However, in case that several tapeworms occur – up to 14 had been diagnosed in a human host – their length is much shorter. In contrast to *Taenia* tapeworms, *D. latum* worms possess an uterus opening in each proglottid, so that eggs occur in large numbers in the stool of infected persons or animals. The excreted proglottids are mostly completely empty. The eggs have a size of $60\text{--}70 \times 45\text{--}55 \mu\text{m}$ and are unembryonated when excreted. If these eggs are rinsed into salt waters or brackish or freshwater ponds, the larval development starts and a ciliated stage (coracidium) hatches from the egg shell containing the typical infectious six-hooks-larva. First intermediate hosts are copepods, which ingest the swimming coracidia. The further life cycle is diagrammatically represented in Fig. 1.

Symptoms of Disease (Diphyllobothriasis)

Infections with *D. latum* may remain symptomless for long. Often, only after 10–15 weeks or even after years, a severe complication may occur, when an anemia of the perniciousa type occurs (due to extraction of vitamin B₁₂ from the human intestine). This anemia especially occurs when the worms have been attached in the duodenum by its two groove-like suckers close to the pylorus. The anemia then introduces often severe symptoms of weakness, paresis, paresthesias, disturbances during walking, vomiting, etc.

Diagnosis

The method of choice is the microscopic search for the $60\text{--}70 \times 45\text{--}55 \mu\text{m}$ sized eggs, if the typical proglottids (Figs. 2, 3) are not found

***Diphylobothrium latum*, Fig. 1** Life cycle of pseudophyllidean cestodes. A “► *Diphylobothrium latum*” inhabits the intestine of humans, cats, dogs, and other fish-eating animals (final hosts), being attached to the intestinal wall with two longitudinal bothria. B “► *Schistocephalus solidus*” occurs in the intestines of a wide range of fish-eating birds (*Ligula intestinalis* has a very similar life cycle). 1 Final hosts. 2 Adults. *D. latum* reaches often a size of 20 m; its mature proglottids are broader than long; coils of the gravid uterus form a centrally located rosette. *S. solidus* is lanceolate-shaped with a size of 5–8 × 1 cm, “► bothria”-like apical indentations are of poor adhesive power. 3 The operculated eggs are

excreted unembryonated; completion of development to coracidium larvae (3.1.) takes one to several weeks depending on the water temperature. 4 Free “► coracidium” larva containing the oncosphaera which is endowed with 6 hooks. 5–6 Having ingested free coracidia several species of copepods are suitable intermediate hosts within which development of second-stage larvae (“► Proceroid”; 6) occurs. 7–8 As second intermediate hosts, brackish and freshwater fish become infected by ingesting infected copepods. Inside the intestine the proceroid is released, and eventually bores its way into the body cavity and muscles where it grows rapidly into a plerocercoid (“► Sparganum”). In *D. latum* the

Diphyllobothrium latum,

on/in stools. Concentration methods of choice are “► **S.A.F.C.**” and “► **M.I.F.C.**,” since “► **Flotation**” is not useful. Serological methods are not very successful, and eosinophilia does mostly not occur.

Infection

Oral uptake of plerocercoid larvae in raw meat of the intermediate hosts (fish). These larvae grow up within 21–24 days to adult tapeworms that start excretion of eggs/proglottids.

Prophylaxis

Avoid eating raw or undercooked fish from brackish or fresh waters in endemic regions.

Incubation Period

Three weeks, if symptoms occur at all

Prepatent Period

Twenty-one to twenty-four days (= the first appearance of proglottids in stools)

Patency

Up to 10 years

Therapy

Drug of choice is praziquantel (2.5–5 mg/kg bodyweight). Niclosamid (1 × 2 g) is also effective. Substitution of vitamin B₁₂ is recommended.

Diphyllobothrium latum, Fig. 1 (continued) plerocercoids remain mainly undifferentiated, whereas in *S. solidus* the plerocercoids show the main features of the adults (i.e., division into 62–92 proglottids and the presence of genital anlagen; however, they are not yet fertile). Unlike *D. latum*, the progenetic plerocercoids of *S. solidus* are extremely specific in their host, developing only in the body cavity of the marine and freshwater forms of the 3-spined stickleback (*Gasterosteus aculeatus*). 8.1 In *D. latum* “► **plerocercoids**” may become accumulated without further development in the muscles (not encysted) of carnivorous fish (paratenic hosts). 9 Infections of final

hosts occur by ingestion of raw meat of fish containing plerocercoids. Having reached the intestine the plerocercoids of *D. latum* grow rapidly and become adult worms in 5–6 weeks, whereas *S. solidus* plerocercoids mature rapidly (within 36–48 h) and release eggs. Humans, who accidentally eat meat or fish containing plerocercoids of other nonhuman pseudophyllidea may also become infected; however, plerocercoids do not mature, but creep around inside the human body, leading to a disease called “► **sparganosis**.” *CI* cilia, *GP* genital pore, *HK* hooks of *ON*, *ON* oncosphaera, *OP* “► **operculum**,” *OU* opening of the uterus, *UT* uterus, *VI* “► **vitellarium**”

Diphyllobothrium Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

D. klebanovski and *D. nihonkaiense* are described in East Asian countries. *D. dendriticum* occurs in Europe, parasitizes in freshwater fish and in humans and *D. pacificum* is found in South America (especially common in Chile and Peru). The life cycle of these species is very similar to that of ► *Diphyllobothrium latum*.

Diphyllobothrium Species Rare Cases

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Table 1 summarizes *Diphyllobothrium* species, which occur naturally in free-living animals and in rare cases also in humans (see Andreassen 1998).

Diphyllobothrium Species Rare Cases, Table 1

Species	Main final hosts	Region
<i>D. alascense</i>	Burbot (<i>Lota lota</i>)	Alaska
<i>D. cameroni</i>	Unknown	Kamerun
<i>D. cordatum</i>	Seals, walruses, dogs	Greenland, Iceland
<i>D. dalliae</i>	Dog, Arctic fox	North America (Alaska)
<i>D. dendriticum</i>	Fish-eating birds (e.g., gulls); mammals including humans	Circumpolar
<i>D. hians</i>	Seals	Japan
<i>D. honghtoni</i>	Dogs, cats	China
<i>D. klebanovski</i>	Bears	Far East
<i>D. nihonkaiense</i>	Seals	Japan
<i>D. orcini</i>	Sea lions	Japan
<i>D. pacificum</i>	Sea lions	Peru, Japan, Ecuador
<i>D. scoticum</i>	Sea lions	Japan
<i>D. ursi</i>	Bears	North America
<i>D. yonagoense</i>	Seals	Japan

This species, which normally parasitizes in
whales, is also found occasionally in humans in
Japan.

Diplomonadida

Classification

Order of ► [Mastigophora](#).

General Information

The diplomonadids are characterized by the
occurrence of a symmetrically arranged
double set of each group of organelles
(► [Giardia lamblia](#), Fig. 1). This unique appear-
ance may be explained by the omission of cellular
division after reduplication of organelles. The
species of diplomonadids (Table 1) inhabit the
intestines of their hosts, where they are attached
to the ► [microvilli](#) (► [Giardia lamblia](#), Figs. 2
and 3) by means of their ventral sucker-like sur-
face and feed by ► [pinocytosis](#) on the intestinal
fluid (► [Endocytosis](#), Fig. 1). Reproduction pro-
ceeds as longitudinal ► [binary fission](#) of the intes-
tinal ► [trophozoites](#), whereas transmission from

Diplopylidium

Genus of the tapeworm family Dipylidiidae. *D. noelleri* and *D. acanthotetra* are found in cats and dogs. The egg package (cocoon) contains only a single egg.

Diplostomatidae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *diploos* = double; *stoma* = mouth.

The name of this family of digenetic trematodes comes from the erroneous belief that the ventral sucker is also surrounding an intestinal opening as does the anterior mouth sucker. However, the ventral sucker is just an acetabulum-fastholding system. The most commonly known species in this group is ► *Alaria allata*, which reaches as adult digenetic worm a size of $2.5\text{--}6 \times 0.5\text{--}2$ mm in the intestine of canids such as dogs, foxes, wolves, etc.). In foxes, about 30 % are infected as was seen in studies in Europe. First intermediate hosts are freshwater snails; second intermediate hosts are larvae of frogs. Several amphibian, reptilian, or mammalian species may become so-called paratenic

hosts, in case they live in the water biotope and feed infected specimens of second intermediate hosts. Interestingly, even wild pigs may become such paratenic hosts since mesocercariae had been found in their muscles being described as stages of ► *Agamostomum* or ► *Duncker's muscle cones*.

D

Classification

Order of Insects.

Important Species

See Table 1.

General Information

The usually ectoparasitic and only seldom endoparasitic dipteran species show the following common features, although their basic body organization is modified according to their different ways of living:

- The pair of forewings is always present; the hind wings have been reduced to so-called halteres (► [Peritrophic Membranes](#)/Fig. 1).
- Eyes are in general large compound ones composed of numerous ommatidia (Insects/Figs. 8, 9).
- Mouthparts are of the licking-sucking type (in true flies) or of the biting type (in blood-sucking species).
- The life cycle runs as ► [holometabolous development](#) including apod (feetless) larvae, a non-feeding or even immotile ► [pupa](#), and ► [dioecious](#) adults (Fig. 1).
- Larvae and adults may live as parasites; larvae in general as endoparasites, and adults as ectoparasites. With the exception of a few species (► [Hippoboscidae](#)), the adult dipterans feed periodically on their hosts (Table 1).

Life Cycle

See Fig. 1.

Morphology

See Figs. 2 and 3.

Dipteraviridae

Viruses transmitted by dipteran insects (e.g., flies and ► [mosquitoes](#)).

Dipylidiasis, Man

Disease due to the infection with the tapeworm ► [Dipylidium caninum](#) which is common in cats and dogs. Infection occurs via oral uptake of tapeworm larvae in crushed ► [fleas](#).

Diptera, Fig. 1 Developmental stages in the holometabolic life cycle of important groups of Diptera (cf. Table 1). Note that several larval stages may occur; temperature and other conditions regulate the developmental speed. 1 Family ► *Simuliidae* (► *Blackflies*). The 2–5 mm long females of ► *Simulium* spp. usually feed diurnally on blood of their hosts (► *Pool Feeders*), but males do not suck blood. The filtering larvae and the non-feeding pupae are enclosed in cocoons (not drawn) that are attached to the surface of objects submerged in swiftly running waters. 2 Fam. ► *Glossinidae* (*Tsetse Flies*). Both sexes of the 6–14 mm long ► *Glossina* spp. feed on blood of their hosts (pool feeders). Females pass at once a single fully grown third-instar larva which has developed inside the uterus with the aid of symbionts and uterine

glands. The pupation occurs in protected areas of the soil. 3 Fam. ► *Ceratopogonidae* (biting ► *midges*). The members of the (drawn) genus ► *Culicoides* are very small (1–4 mm long). Females suck blood of their hosts. Larval development proceeds in wet, semisolid media or even in the holes of trees. 4 Fam. ► *Phlebotomidae* (► *Sand Flies*). The members of the (drawn) mammal-biting genus ► *Phlebotomus* are about 2.5 mm long and are characterized by numerous body hairs. Females suck their hosts' blood during the night. Larval development (four instars) proceeds in wet soil. 5 Fam. ► *Muscidae* (houseflies). *Musca domestica* lays its eggs on urine- and dung-contaminated stable refuse, where larval development (three instars) proceeds. ► *Musca* is saprophagous, whereas both sexes of ► *Stomoxys calcitrans* feed on blood

Dipylidiasis, Man, Fig. 2 A typical egg-cocoon of *Dipylidium caninum*

Main Clinical Symptoms

► [Diarrhoea](#), ► [urticaria](#), loss of weight, and anal ► [pruritus](#).

Incubation Period

10–25 days.

Prepatent Period

19–25 days.

Patent Period

1 year.

Diagnosis

Occurrence of typical proglottids in the faeces (Figs. 1 and 2).

Prophylaxis

Deworming of dogs, cats, and treatment against fleas.

Therapy

Treatment with praziquantel, see ► [Cestodocidal Drugs](#).

Dipylidium caninum

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *dis* = two; *pyle* = pore. Latin: *canis* = dog. English: cucumber seed tape worm (rice grain tapeworm).

Dipylidium caninum, Fig. 2 Light micrograph of the scolex region of *D. caninum* showing the protruded rostrum

Dipylidium caninum, Fig. 4 Light micrographs of three terminal proglottids of *D. caninum*

Dipylidium caninum, Fig. 3 Macrophoto of the terminal region of an excreted adult worm of *D. caninum*. The arrows point to borders of the terminal proglottids

egg packages, which measure $200 \times 120 \mu\text{m}$ and contain 8–30 eggs with diameters of $34\text{--}40 \mu\text{m}$ (Fig. 1.2). The excreted terminal proglottids appear in the feces of the host and have at first the appearance of whitish cucumber seeds and later (when dried) appear as rice grains. This appearance led to the trivial names “cucumber seed tapeworm” respectively “rice grain seed worm.” If these eggs are swallowed by flea larvae or mallophages, a typical cysticercoid larva develops inside their body, which is infectious for the final host (Fig. 1.4).

Dipylidium caninum, Fig. 5 Diagrammatic representation of the sliding behavior of a dog infected with *D. caninum* (drawing by Dr. Walldorf)

Symptoms of Disease (Dipylidiasis)

The most prominent symptom is an intense itching in the anal regions which leads to the “sliding” reaction of dogs and cats (Fig. 5). Besides these symptoms, huge infections may introduce disturbances in digestion, loss of weight, and rough hair. In humans, 100–200 worms introduced bloody diarrheas and

***Dipylidium caninum*, Fig. 6** Light micrograph of an egg package of *D. caninum* containing several infectious eggs

abdominal cramps, loss of weight, strong urticarial reactions, and eosinophilia.

Diagnosis

Demonstration of the typical whitish terminal proglottids (Fig. 4) and microscopical observation of the typical egg packages (Fig. 6), which can be obtained by help of concentration methods (“► S.A.F.C.,” “► M.I.F.C.”).

Infection

Oral uptake of portions of infected intermediate hosts by mouth contact with contaminated hair of infected dogs or cats.

Prophylaxis

Cleaning of dogs and cats from fleas or mallophages when kept in households.

Incubation Period

10–25 days

Prepatent Period

2–3 weeks

Patency

About 1 year

Therapy

Drug of choice is praziquantel (1×5 mg/kg bodyweight) for humans and animals. Dogs and cats should also be treated with insecticidal products (see “► fleas”) to avoid new infections.

Dirofilaria immitis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *dirus* = announcing mischief; *filum* = filament; *immitis* = severe, hard. English: heartworm

Geographic Distribution/Epidemiology

Worldwide. This species is found in carnivores (mainly dogs, cats, and relatives) but also in humans. It is estimated that millions of carnivores are infected in most regions of the tropics and subtropics, since, e.g., in Italy and Spain, prevalence rates of up to 80 % were found in dogs and up to 24 % in cats. Also, high numbers (several hundred thousands) of humans and free-living primates should be infected.

Morphology/Life Cycle

The adult worms (♀ and ♂) live in the right heart chambers and in the arteria pulmonaris, mainly of dogs and other canids. The females reach a length of up to 20–30 cm (Figs. 1, 2). Males are only 18 cm long at the maximum, and their spirally coiled posterior end shows two rows of five preanal papillae and two rows of six postanal papillae. Their two spicula have different lengths reaching 180–300 µm and 300–375 µm. The

nonsheathed microfilariae measure about 220–340 µm (Table 1) and appear mainly between 6 and 10 p.m. in the peripheral blood (= nocturnal cycle).

***Dirofilaria immitis*, Fig. 2** *Dirofilaria immitis*. Open heart of a dog showing the whitish slender worms that may block the blood vessels

***Dirofilaria immitis*, Fig. 1** *Dirofilaria immitis*. Life cycle of the heartworm *Dirofilaria immitis*. 1–3 During blood meal of female mosquito larvae 3 are transmitted, which wander via lung to the heart and reach maturity within 6 months. While growing to a maximal length of

20–30 cm they may block the pulmonary arteries. 4 After copulation the females produce unsheathed microfilariae (MF) of about 220–240 µm in length. AA adult worms in artery, MF microfilariae

Dirofilaria immitis, Table 1 Criteria for differential diagnosis of microfilariae

Criteria	<i>Dirofilaria immitis</i>	<i>Dirofilaria repens</i>	<i>Dipetalonema dracunculoides</i>	<i>Acanthocheilonema^a reconditum</i>
Length (µm)	220–340	205–360	220–280	185–260
Shape of tail	Straight	Stumpy	Straight or hook-like	Straight

^asyn. *Dipetalonema*

Dirofilaria immitis,
Fig. 3 *Dirofilaria immitis*
worm from dog’s heart

The sexual opening of the females has its position close to the anterior end and has just 3 mm distance to the oral region. The transmission from one host to the other occurs by help of mosquitoes as intermediate hosts. Many species of the genera *Aedes* (e.g., *Aedes vexans* in Europe) and *Culex* (e.g., *Culex pipiens* in Europe) act as vectors. They ingest unsheathed microfilariae (= first larvae) within their blood meal. Inside their body, the infectious larva 3 is developed in temperature-dependent time (e.g., it needs 30 days at 18 °C but only 8 days at 20–24 °C). This larva 3 finally enters the proboscis of the female mosquito, leaves during a bite act the head of the mosquito, and enters the skin via the biting channel. The larva 3 molts to larva 4, which wanders within the subepidermal tissues, reaches the stage of a preadult there at a length of 2–3 cm, and then penetrates the right heart chamber and the arteria pulmonaris, where within 6–9 months

maturity is reached and the production of microfilariae is started. Life time of adult reaches up to 7 years (at least in dogs, while only 2 years in cats) (Figs. 2, 3, and 4).

Symptoms of Disease

In **dogs**, the following symptoms are common: chronic cough, dyspnoea and vomiting, shock reactions with internal hemolysis (combined with brownish appearance of the urine as outer sign of the vena cava syndrome). Pneumonia is common as well as edema, ascites, and dermatitis as well as severe heart problems due to the length of the worms.

In **cats**, mostly no or low-graded symptoms occur; however, sudden deaths have been reported due to arteria stenosis by block worms.

***Dirofilaria immitis*, Fig. 4** Light micrograph of a Giemsa stained microfilaria of *Dirofilaria immitis*. RBC red blood cell

Diagnosis

Blood smears of microfilariae obtained by blood filtration or by use of the Knott method should be done with blood obtained between 6 and 10 p.m., since the microfilariae are only periodically during these hours in the peripheral blood. In order to obtain significant chances for positive results, at least 1 ml of EDTA blood must be investigated. Morphological determination of the species is difficult (Table 1). Thus, investigation of the sites of acid phosphatase along the larval body is needed. Antibody reactions give only diffuse information. Therefore, heart investigations using different methods are strongly recommended if search for microfilariae remained negative.

Infection

During blood meal of infected mosquitoes (*Aedes*, *Culex*).

Prophylaxis

Protection of dogs and humans by repellents. Treatment of dogs with ivermectin ($1 \times 6 \mu\text{g/kg}$ body weight; p.o.), milbemycine ($1 \times 0.5\text{--}1 \text{ mg/kg}$ body weight; p.o.) before entering endemic regions. The last dose should be given 30 days after the leave of an endemic region.

Incubation Period

First clinical symptoms appear after 3 months or later.

Prepatent Period

Microfilariae appear 6–9 months after infection.

Patency

Dogs: up to 7.5 years; cats: up to 2 years; humans: unknown

Treatment

The chemotherapeutical treatment of adult filariae is difficult. Thus, surgical removal is probably the method of choice. Melarsamin ($2 \times 2.5 \text{ mg/kg}$ body weight at an interval of 3 h) injected deeply into the muscles is highly effective. However, dead worms inside the heart cause problems!

Dirofilaria repens

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: *dirus* = bad future, preordain; *filum* = fine thread, filament; *reperere* = creep. English: Moving skin filariasis.

Geographic Distribution/Epidemiology

This worm is found in the subcutaneous tissues of dogs, cats, wild carnivores, and (occasionally) in humans in Europe and Eastern countries. Most infections are asymptomatic.

Morphology/Life Cycle

Adult females reach a size of 13–17 cm × 450–650 μm (Fig. 1), while the males are considerably shorter and have a length of 5–7 cm. Adult female worms live in nodules under the skin and release microfilariae (330–370 μm × 6–8 μm) into the bloodstream. Such circulating microfilariae are taken up by females of many species of mosquitoes (genera *Aedes*, *Anopheles*, *Culex*) and develop (temperature dependent) in 20–30 days into the infectious larvae 3, which is finally again transmitted to a vertebrate host, where the adults reach maturity within 6–9

Dirofilaria repens, Fig. 1 Diagrammatic representation of the life cycle of *Dirofilaria repens*. 1 During a mosquito bite the infectious larvae 3 are transmitted to hosts (dogs and humans). 2, 2.1 Inside dogs and humans the larvae 3 move to the subcutaneous tissues and grow up within 5–9 months to mature adults, two of which in cross sections (3) show the coiled uterus (green) containing the microfilariae. 4 The adult worms live in nodules under the skin and

release microfilariae (= larva 1), which circulate in the blood. 5, 6 Cycle starts again when mosquitoes swallow microfilariae during their blood meal. These microfilariae develop inside the mosquito within 10–30 days (depending on the temperature into the infectious larvae 3, which enters during the blood meal the biting channel and thus infects the next host) (According to Genchi et al. 2013)

months (Fig. 1). In humans, however, maturity is mostly not reached.

Symptoms of Disease

Infections of dogs, cats, and **humans** remain in most cases asymptomatic and thus the infections continue for a long time undiagnosed. Infected dogs and cats are reservoir hosts for human infections especially in cases of relocation of dogs from endemic regions in South and Southeast Europe to Northern countries such as Germany, Poland, and Hungary. Although in many cases no or low graded symptoms of disease occur in dogs and cats, several cases of severe infections of humans had been described (more than 1,000 documented cases). The growing adults were mainly found in nodules in the subcutaneous tissues, but they also occurred in the eyes, in the female breast, in the male genitalia, and in the lungs. Localization in skin can be diagnosed as weak, wandering swellings leading eventually to inflammation and itching.

Diagnosis

In cats and dogs infection is best shown when using the ► [Knott test](#) to detect the bloodstream microfilariae. Since in humans only rarely microfilariae are found, mostly only surgical dissection of wandering stage shows an infection.

Infection

Infectious larvae 3 enter the skin of hosts during bites of mosquitoes.

Prophylaxis

Protection against bites of potentially infected mosquitoes is the use of repellents by humans and domestic animals. Humans can be protected by compounds like DEET or ► [icaridin](#) = ► [saltidin](#) (e.g., Autan[®], Viticks[®]).

Dogs and cats can be protected by long-lasting repellents (e.g., moxidectin/imidacloprid) or by oral application of macrocyclic lactones (e.g., ivermectin, moxidectin, selamectin).

Incubation Period

Several months, if symptoms occur at all.

Prepatent Period

Six to nine months, until adults have finally grown up. **Attention:** In humans mostly no microfilariae are produced.

Patency

Five to seven years.

Treatment

Recent studies have shown that macrocyclic lactones are very efficacious against *Dirofilaria* species. For details, see ► [Dirofilaria immitis](#).

Dirofilaria Species in Europe

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Originally the species ► *Dirofilaria repens* and ► *D. immitis* were known from regions around the Mediterranean Sea. In recent years, however, both species have spread significantly and are found in countries far from the Mediterranean regions (up to 53° North), and prevalence rates increased considerably reaching 6–47 % of investigated dogs. With respect to high numbers of positive DNA tests of such worms in mosquitoes, the hidden infection rate should be considerably high. Thus mosquito protection of dogs and humans is reasonable.

pulmonary artery branch, which they thrombus (► [Pathology](#), Fig. 28B) giving rise to a localized pulmonary infarct. The worm is usually dead in the thrombus. The release of worm antigens provokes an intense hypersensitive reaction, with central necrosis accompanied by eosinophils and a granulomatous or fibrotic reaction peripherally. Some of the older lesions calcify and become visible on radiological examination of the chest.

Main Clinical Symptoms

Undifferentiated heart pain, hypertrophy of heart, ascites.

Incubation Period

3–9 months.

Prepatent Period

7–9 months.

Patent Period

6–7 years (at least in dogs).

Diagnosis

Difficult, since no microfilariae are formed in humans; serological tests.

Prophylaxis

Avoid bites of mosquito vectors.

Therapy

Treatment see ► [Nematocidal Drugs](#), [Man](#).

Dirofilariasis, Man

Synonyms

Zoonotic filariasis.

Pathology

Dirofilariasis is an infection of dogs, raccoons, bears, etc., caused by ► *Dirofilaria immitis*. It is occasionally transmitted by ► [mosquitoes](#) to humans. The young adult worms wander to the right heart and are usually propelled into a

Discrete Typing Units (DTUs)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

It was found that in disease due to *Trypanosoma cruzi* infections many variations occur. They are claimed to be included by several so-called discrete typing units (DTUs). There exist apparently six different DTUs, which differ in their geographical distribution, ecological niches, vectors, and reservoir hosts as well in the severity of

induced clinical symptoms. Each DTU is apparently based on a variety of strains of the parasites.

Disease Control, Epidemiological Analysis (Wernsdorfer, Vienna)

Parasitic diseases originate from an interplay between parasite, vector or carrier, and principal host in an environment that is suitable for the parasite's maintenance or propagation. It is customary to differentiate broadly between food-borne, water-borne, arthropode-borne, and directly invasive parasitoses. However, this rather coarse classification will be of little use in identifying targets of control intervention.

Some of the principal modes of infection are given in Table 1, but this grouping does not provide more than a summary ► [orientation](#). With the individual parasitoses it will be indispensable to analyze, in detail, all stages of the parasite's life cycle and the biological and environmental factors governing its transmission, i.e., to consider the epidemiology of the disease. As an example, the main epidemiological components of the ► [malaria](#) situation are summarized in Table 2. The resulting picture will be specific for a given area and important inter-area differences are commonly seen. Since the epidemiological situation may change over time, resulting from modifications of environment, host – vector relationships and other factors, the analysis requires regular updating. The approach to analyzing the factors governing the transmission of other parasitic diseases is similar, and should yield the elements required for the identification of targets of intervention.

Mathematical models can be quite useful in epidemiological analysis inasmuch as they facilitate a quantitative appreciation of particular features in the parasite's life cycle and permit

Disease Control, Epidemiological Analysis (Wernsdorfer, Vienna), Table 1 Principal modes of infection in parasitic diseases of man and other animals (according to Wernsdorfer)

Mode of infection (principal host)	Examples of parasite species
No alternation of host species	
Ingestion of infective stage, followed by self-replication within principal host	<i>Hymenolepis nana</i>
Ingestion of infective stage, often followed by self-contamination (immediate infectiousness)	<i>Enterobius vermicularis</i>
Ingestion of infective stage the development of which requires a period of non-parasitic existence in a suitable environment	<i>Ascaris lumbricoides</i>
Active invasion of infective stage the development of which requires a period of non-parasitic existence in a suitable environment	<i>Ancylostoma duodenale</i>
One or several alternations of host species	
Ingestion of free infectious stage (often on carrier material)	<i>Fasciola hepatica</i>
Ingestion of infectious stage within alternate host	<i>Gnathostoma spinigerum</i>
Active invasion of free infective stage	<i>Schistosoma</i> spp.
Active invasion, through bite wound inflicted by alternate host	<i>Wuchereria bancrofti</i>
Introduction of infective stage with insect bite at blood meal	<i>Plasmodium</i> spp.
Deposition of infective stage with faeces of vector at time of blood meal	<i>Trypanosoma cruzi</i>

Disease Control, Epidemiological Analysis (Wernsdorfer, Vienna), Table 2 Major factors related to the transmission and control of malaria (according to Wernsdorfer)

Parasite	Human host	Anopheline vector	Environment
Species	Susceptibility to infection	Species	Topography (plains, hills, valleys)
Pathogenicity	Relative immunity (age)	Susceptibility to infection	Surface water (types, extension, depth, seasonality)
EE and E schizogony	Gametocytaemia	Feeding habits (hosts)	Vegetation
Recrudescence pattern	Exposure to vector contact	Feeding frequency (gonotrophic cycle)	Agricultural utilization
Relapse pattern	Occupation	Resting habits	Meteorology

projections of the expected efficacy of specific interventions. Such models exist for malaria and some other diseases of major public health importance. The quality of results obtained from such

models depends primarily on reliability and exhaustiveness of the data input (► [Mathematical Models of Vector-Borne Diseases](#)).

Disease Control, Evaluation

The control of parasitic diseases has the purpose of reducing the burden caused by such diseases in the human population or in livestock, or both. The control programmes are usually supported by public funds. The planning of such programmes should be sound and based on a realistic strategy and target projections, and a reasonable expectation of success. The performance and efficacy of control measures should therefore be subject to monitoring as the basis of regular and continuous evaluation.

Parasitic diseases span a wide spectrum of severity and impact on human or animal health. On the other hand, the target levels of control may vary, dependent on technical and financial feasibility. Realistic planning should take these limitations into account. Whenever a plan of operation is drawn up, monitoring and evaluation should be integral components of it.

The selection of monitoring tools is determined by the methods of intervention which might be relatively simple or complex, depending on the disease and the envisaged targets of intervention. In the following, examples of the choice of monitoring tools are given for some major tropical parasitic diseases.

In the control of African trypanosomiasis caused by *Trypanosoma brucei rhodensiense*, for instance, the early detection and treatment of human trypanosomiasis will be the objective of control as long as the effective control of the vector population (*Glossina morsitans* group) and the sanitation of wildlife reservoir are not feasible. In this case morbidity and mortality from the human infection will be the primary parameters for monitoring, supported by quality control monitoring related to diagnosis and treatment of the disease.

The control of American trypanosomiasis, Chagas disease, is mainly based on the control of the vectors (reduviid bugs). While the diagnosis of infections with *T. cruzi* has become easy due to the development of reliable immunodiagnostic tests, the treatment continues to pose problems due to poor tolerability and relatively low efficacy

of available medicaments, particularly in the management of chronic disease. The major operational approach relies currently on the prevention of future infections by environmental sanitation, i.e., reduviid-proofing of human habitations and animal shelters, which are simple and technically feasible measures applicable at low cost. In this case, the criteria for monitoring and evaluation of control measures will be the number of structures targeted for improvement and those actually improved as well as the adequacy of improvement work, in addition to a thorough search for structures missed, but deserving improvement. In addition, regular monitoring of the specific seropositivity rate for *T. cruzi* in the areas subject to housing improvement, and particularly the absence of new infections, will reflect the impact of the control measures.

The control of lymphatic filariasis caused by *Wuchereria bancrofti* relies mainly on the annual mass single-dose administration of ivermectin and albendazole that is also the principal tool adopted for eradicating the disease in scheduled areas. In urban areas endemic for lymphatic filariasis, this measure is usually complemented by vector control (*Culex* spp.). Effective monitoring of mass drug administration requires geographical reconnaissance and detailed population census in the entire operational area; information that needs regular updating. Monitoring criteria are the coverage of mass drug administration in the scheduled population, the prevalence of infections with *W. bancrofti*, measured by microscopic diagnosis or antigen-detection tests, the incidence of new infections, and the prevalence and new occurrence of advanced clinical forms of lymphatic filariasis such as lymphoedema and elephantiasis. In addition, monitoring requires quality control of the diagnostic procedures. The complementary vector control operations need to be evaluated for the degree of coverage achieved in the detection and the sanitation potential confirmed breeding places, if possible supported by regular checking of vector density.

In malaria control the type of intervention will be largely determined by the envisaged and feasible target level. There are, basically, three target levels:

1. The elimination of mortality and the reduction of suffering from malaria
2. The elimination of mortality from malaria and the reduction of malaria prevalence, expressed in a significant decrease of morbidity
3. The elimination of malaria from a particular area or country

While the first objective can be reached by early diagnosis and treatment of all malaria cases, the achievement of the second objective usually requires also vector control measures and disease surveillance. The realization of the third objective necessitates rigorous precision in the performance of focus recognition and elimination as well as perfect coverage by disease surveillance in space and time.

The elimination of mortality from malaria is usually the objective in areas where the currently available tools for malaria control are insufficient for achieving the reduction of prevalence of and morbidity from malaria. The goal can only be achieved by the competent operation of adequate diagnostic and curative facilities. Countries having adopted this primary objective, mainly in Africa, are still far from having established such adequate facilities. More than 80 % of all “clinical” malaria cases are treated for falciparum malaria without laboratory-based diagnosis, thus unnecessarily increasing non-target drug pressure and promoting drug resistance. Here the structural and functional improvement of the health service infrastructure is the prerequisite for achieving the full coverage of the population in space and time which can ensure early recognition and treatment of true malaria cases. Such a system of evidence-based treatment requires continuous quality control at all levels and back-up by competent tertiary treatment facilities for the referral and management of patients with severe or complicated malaria. The key parameter for measuring success will be the mortality from malaria, but continuous monitoring of the efficacy of routine treatment will also be required in order to recognize therapeutic failure and to prevent avoidable mortality.

In areas aiming at the reduction of malaria prevalence, the type of appropriate interventions will depend on the baseline degree of prevalence

and morbidity. Usually it will require the application of vector control measures for the rapid reduction of malaria transmission and the building up of surveillance and focal sanitation activities to replace blanket vector control when the annual inoculation rate has dropped below 0.1 %. Usually, such operations will be carried out in the framework of the general health infrastructure under the guidance of a specialized technical service. Given the complexity of operations, the criteria for monitoring encompass a relatively wide range and need to be adapted according to the progress of the control programme. The monitoring activities related to the vector control aspects depend on the selected operational methods, e.g., larval control by environmental sanitation, larviciding or deployment of larvivorous fish, or control of adult anopheline vectors by intradomestic application of residual insecticides. Here the validity and updating of geographical reconnaissance, the degree and regularity of operational coverage as well as the quality of material and logistics will be criteria for evaluation, complemented by the regular assessment of important entomological indices in well-chosen sentinel areas. These indices may, *inter alia*, include anopheline density, parous rate, human blood index, stability index and calculation of the inoculation rate. With regard to the disease-based parameters it will initially suffice to monitor the prevalence and the monthly and annual incidence of malaria, the area- and age-specific slide positivity rates and the quality of diagnostic and therapeutic activities. With the implementation of surveillance the time has come for ensuring and monitoring quality and coverage of case detection, diagnostic and therapeutic activities in space and time, and the epidemiological classification of all malaria cases detected in the course of surveillance. These activities include the post-therapeutic follow-up of malaria cases and, if so indicated, revision of the treatment policies as well as the application of remedial focal vector control operations.

The achievement of the third and highest target level, i.e., the elimination of malaria from a larger geographical area or country may be attempted if preceding malaria control operations have shown

consistent success and the likelihood of feasibility, based on an adequate and functionally competent service infrastructure. The indices for evaluation are essentially the same as those in the advanced phases of malaria control. Quality control of all aspects of passive case detection, diagnostic and therapeutic procedures, rapid implementation of epidemiological investigation and remedial focal measures need to be brought to near perfection. Once autochthonous malaria transmission has ended, the vigilance activities should be devoted to the rapid detection of imported malaria cases and preventing the establishment of new foci of transmission.

Disease Control, Methods

General Information

The approaches to the control of parasitic diseases are crucial components of the control strategy. The realization of the various approaches is dependent upon the use of individual measures the selection of which will be determined inter alia by expected efficacy, convenience, economy and acceptability. In most cases a variety of measures will be required simultaneously. This applies particularly to ► [anthropozoonoses](#) and ► [zooanthropozoonoses](#) with highly adaptable biological systems. Such diseases are the most difficult to control, especially if non-domestic animals are involved as reservoirs of infection. Another general aspect is man's awareness of parasitic diseases affecting humans and livestock, and the motivation for taking remedial action. If such broad motivation is lacking among the afflicted population, it is likely that imposed control programmes will have only limited and ephemeral success. Health education in the widest sense, encompassing both the health of humans and of domestic animals, should therefore prepare the ground for a systematic effort against the diseases affecting the community.

The simplest measures for achieving a set purpose are usually the best, but in their planning and

execution due attention should be paid to acceptability, compatibility with cultural and religious background, and technical feasibility. For instance, it would be expecting too much if the dietary patterns of large populations were to be changed abruptly. Here the practical solution will consist of rendering the incriminated food safe rather than banning it. The adoption of particular individual protective measures will depend on the person's economic status. Wearing shoes will generally protect against ► [ancylostomiasis](#), and the use of impregnated bed nets supports protection against ► [malaria](#). However, shoes and bed nets have their price and not everybody may be able to afford them or even be willing to use them. Selection of the most appropriate measures for disease control requires therefore a sound appreciation of advantages, limitations and disadvantages of the methods.

Parasitic diseases encompass a wide range of biological systems. Hence, the control of these diseases has many facets, implying a host of different measures the most important of which are detailed in the following sections.

Water Supplies

Water is one of the most important vehicles of parasitic diseases. It harbours a number of pathogens which can reach the human or animal host through transdermal penetration (e.g., ► [Schistosomiasis, Man](#)) or through ingestion (e.g., ► [Dracunculiasis](#)). It is also the medium through which the larvae of many parasitic species reach molluscan hosts, ultimately to be transmitted to man or livestock as a food-borne pathogen. Safe water is therefore an important means of controlling numerous parasitic diseases, especially ► [helminth](#) infections (in addition to controlling the transmission of non-parasitic water-borne pathogens). Safe water should be available for consumption, bathing, washing and leisure activities. Ideally, piped, treated water should be available for household use. However, this will not be feasible as yet in most of the vast rural areas

in the tropics and the subtropics. Well-maintained deep wells with elevated rims made out of masonry or concrete for the prevention of contamination will be an acceptable and feasible alternative in many places. The use of traditional step wells or ponds should be discouraged, but, if there is no other source, boiling or sieving water through a fine mesh may render it largely innocuous. The installation of a supply of piped, treated water may permit the abolition of unhealthy water collections. There may be public objection to this if the water collections are used for producing food (e.g., fish, crabs) or for the irrigation of crops. However, larger pools can be constructed on a community basis and maintained in such a way that they do not permit the transmission of pathogens while fulfilling the purpose of pisciculture and serving as a source of water for agricultural and household needs.

Excreta Disposal

Most helminth eggs or larvae have to reach water or humid ground for further development. They achieve this as a result of urination or defecation into water or onto wet soil. This may be part of a deliberate pattern, e.g., for the fertilization of family fish ponds in some parts of eastern Asia. In other instances it is due to an ingrained behavioral pattern or due to the lack of appropriate facilities for the safe disposal of excreta, or a lack of incentive for using available facilities. Health education is probably the most important remedial factor in such situations. It is not advisable to embark on a major programme of building latrines before the population is willing to use them. This applies especially to rural areas in which the population has easy access to various types of surface water. The acceptability of latrines or of even better facilities for excreta disposal is usually higher in urban areas where the installation of sewage treatment will also often prove to be feasible and cost-effective. If the right type of sewage treatment plant is chosen, the resulting sludge will be biologically safe and usable as fertilizer.

Agricultural Hygiene

The agricultural, pastoral and piscicultural environment is often intimately associated with the transmission of parasitic diseases. Agricultural labourers may serve as a source of infective material, especially if they do not dispose of their excreta in a safe way whilst in the fields. They are also exposed to a variety of pathogens, particularly in irrigated areas. In addition to these occupational aspects, the use of unsafe biological fertilizers (fecal matter) on vegetables will promote the spread of some parasitoses, e.g., ► [amoebiasis](#) and ascariasis. Another important feature is the grazing of livestock in wetland areas. Again, health education and community efforts towards the development of safe grazing areas, e.g., through drainage, will be required to remedy the situation. Particular precautions should be taken when using wastewater and excreta in agriculture and aquaculture. Improperly managed water resource development entails the risk of the propagation of parasitic diseases. This should be avoided through appropriate water management.

Personal Hygiene

Apart from the obvious impact of unsafe excreta disposal, the lack of personal ► [hygiene](#) is a leading cause of infection with a variety of parasitic pathogens such as ► [Giardia lamblia](#), ► [Entamoeba histolytica](#) and ► [Enterobius vermicularis](#). Washing hands after defecation and before eating would largely reduce the transmission of these pathogens. The use of water and soap would also impede the transition from reversible lymphoedema to irreversible elephantiasis in ► [lymphatic filariasis](#). However, personal hygiene must go further than water and soap. It should include the seeking of treatment if there are symptoms of disease, and the avoidance of dangerous foodstuffs and of situations conducive to the contraction of infections. Health education will be an important vehicle for imparting the necessary knowledge, awareness and habits. This process should start at as early an age as

possible and schools will have to play a major role in this endeavour.

Housing

Siting and type of human habitations are closely related to the risk of contracting certain parasitic diseases. Houses with cracked masonry, mud walls and/or earth floors were found to be a particularly suitable environment for reduviid ► [bugs](#) responsible for the transmission of Chagas disease. Simple housing improvement was found to reduce or even remove the risk of infection. Siting of settlements away from mosquito breeding grounds was an empirical yet highly effective means of protection against malaria. The siting of settlements at a long distance from irrigation canals (accompanied by the provision of safe household water) is an effective preventive measure against schistosomiasis since it will reduce the frequentation of the canals for washing, bathing and swimming.

Type and standard of housing play a major role in allowing the entrance and exit of disease-carrying mosquitos. It also determines the feasibility of mosquito and fly proofing, and the efficacy of ancillary ► [vector control](#) measures such as mosquito coils and knock-down sprays.

Environmental Management

Some measures of environmental management as a means of disease control have been known since ancient times. Environmental management was the mainstay of malaria control before the advent of residual insecticides and synthetic antimalarials. It is making a comeback due to the limitations of other methods. The applicability of such measures in the control of parasitic diseases is very wide. The most important methods belong to environmental sanitation and water management. Water collections of various types are known to be breeding grounds for arthropod vectors of disease and the homestead of intermediate hosts of many helminthic organisms. Unless local economic (piscicultural and agricultural) and

ecological reasons militate against them, filling, levelling and draining operations (drains, canals and use of trees) will be appropriate measures. The same applies to the sanitation of wetlands to be converted into safe land for agriculture and livestock.

Environmental sanitation, including peridomestic areas and the safe disposal of waste, is a field in which individual and community initiative can be used to great advantage, the more so when the necessary equipment is easily available and cheap (e.g., pickaxes and shovels) or obtainable on loan from various government departments (e.g., earth-moving machinery).

Water management applied to water-storage reservoirs (level management) and irrigation systems (watering and drying cycles) will facilitate disease control by rendering the areas unsuitable as a habitat of intermediate hosts or vectors of parasitic diseases. Water management should be an integral part of design and operation of water impoundments and irrigation schemes.

Control of Vectors and Intermediate Hosts

The control of vectors and intermediate hosts of parasitic diseases may, to a large extent, be achieved through environmental sanitation. However, in some situations the applicability of such measures will be severely limited, as in the control of ► [Simulium](#) spp., the vectors of onchocerciasis. Similarly, widespread temporary breeding places occurring during the rainy seasons in the tropics may pose insurmountable obstacles to environmental management. Alternative control approaches are therefore necessary.

At the beginning of the twentieth century mosquito control was improved by the use of light oils and chemicals such as Paris Green. In spite of their efficacy the application of these measures has remained quite limited due to the need for repetitive use and high cost. The introduction of chemical insecticides has not fundamentally changed the situation. Moreover, ecological considerations and non-target effects against aquatic fauna and flora restrict the widespread repetitive

use of insecticides. Chemical larvicides, rapidly biodegradable insecticides with low non-target toxicity, are still useful in the rapid control of epidemics of some vector-borne diseases. The same applies to the control of *Cyclops* spp., the intermediate hosts of ► *Dracunculus medinensis* and various other helminths.

Biological methods for larval control have a long tradition inasmuch as larvivorous fish, e.g., *Gambusia affinis*, have been used since the beginning of the twentieth century. Although appealing as a natural solution to a natural problem, larvivorous fish have a limited usefulness since seasonal and shallow breeding places are not suitable for their maintenance. It may also be difficult to find a local species of larvivorous fish. The introduction of non-local species may have a disastrous impact on the local aquatic fauna and interfere seriously with the production of food fish species.

Bacterial toxins from ► *Bacillus thuringiensis* and ► *B. sphaericus* are selectively directed against mosquito larvae and being used in the control of *Culex* spp. and *Aedes* spp. As the micro-organisms sink to the ground they are not suitable for controlling ► *Anopheles* spp. (surface feeders). *B. thuringiensis* does not reproduce in the breeding places, but *B. sphaericus* does to some extent though not sufficiently to relinquish the need for regular retreatment of the breeding places.

The intradomiciliary application of residual insecticides such as chlorinated hydrocarbons (DDT), organophosphorus compounds (malathion), carbamides (propoxur), fenitrothion and synthetic pyrethroids is suitable and often quite cost-effective for the control of adult endophilic ► mosquitoes. However, the occurrence of specific resistance, aided and abetted by the agricultural use of insecticides of the same chemical groups, the presence of exophilic mosquitoes, increasing cost of insecticides and labour, and rising ecopolitical constraints have reduced their usefulness or applicability. Their use is still important, though, in the control of threatening or manifest epidemics where they are generally applied on a focal basis. These are situations where the ultra-low-volume (ULV) dispersal of

suitable insecticides, may also show rapid effect. On the whole, the use of integrated vector control opens better prospects for an environmentally acceptable control of arthropod-borne parasitic diseases.

Pyrethroid-impregnated bed nets (deltamethrin or permethrin) or impregnated curtains and screens bar or reduce the contact between man and vector. They gained a firm place in malaria control, especially in areas with moderate or intensive transmission. Their efficacy is due to a repellent effect rather than specific insecticidal action, promoting also epidemiologically desirable vector deviation to animals.

The control of aquatic snails continues to present a serious problem. Environmental management is the only effective and widely acceptable procedure for snail control. The available molluscicides are either not sufficiently effective (e.g., copper sulfate) or they are too toxic for the non-target fauna, including fish.

Diagnosis

The ability to diagnose the presence of infections is an important factor in guiding the treatment of individuals, and forms the basis of epidemiological assessment which should enable the health authorities to determine the dimensions of the specific human and/or animal health problem. It is also an essential tool for monitoring the impact of disease control activities. Macroscopic and/or microscopic diagnosis of parasitic diseases may be relatively simple and reliable with some parasite species, especially intestinal helminths, but exceedingly difficult with others, mostly tissue-dwelling parasites, e.g., certain types of ► nematodes. Serological methods based on the detection of specific antibodies usually reflect past or present host–parasite contact and therefore do not provide proof of current infection. Similarly, relatively fresh infections may not have given rise to detectable antibodies as yet and show seronegativity in spite of the living pathogen's presence. Demonstration of circulating antigens is a more reliable and specific basis for diagnosing current infections. Rather simple and reliable antigen

detection tests have been developed for several human parasitoses, e.g., infections with *P. falciparum* or *W. bancrofti*. They are based on the detection of highly specific parasite antigens. However, relatively high costs continue to restrict their use in the framework of control programmes. The same still applies to tests for the detection of lactate dehydrogenase from malaria parasites.

Identification of infections by polymerase chain reaction (PCR) has been developed for numerous parasite species. However, the routine use of PCR is currently limited to research institutions and to diagnostic laboratories in prosperous countries. Its cost and operational requirements are too high to be affordable by most of the tropical countries.

In order to be widely practicable, diagnostic techniques for the most important human and animal parasitoses must be simple, cheap and undemanding in terms of sophisticated equipment, electricity supply and operator skill. Human and veterinary health services in many parts of the world still lack the infrastructure required for establishing reliable data on prevalence and incidence of major parasitic diseases and associated mortality. This accounts for serious deficiencies in national and international disease statistics.

Treatment

Effective agents for the treatment of numerous parasitic diseases are available (see chapters on disease control). Some are reasonably cheap, such as those for the treatment of intestinal nematode infections of humans and domestic animals. Other medicaments are expensive, such as third-line drugs for the treatment of falciparum malaria. High costs may limit their use or encourage sub-optimal medication, and consequently allow a parasite reservoir to be maintained that will be an obstacle to the effective control of the disease concerned. There are, however, a large number of parasitoses for which the therapeutic armamentarium is grossly deficient, e.g., Chagas disease, kala-azar and liver fluke infections.

With regard to malaria the situation was relatively satisfactory after the wider introduction of the 4-aminoquinolines in the late 1940s. However, the advent of chloroquine resistance in *P. falciparum* has compromised the efficacy of this group of drugs in wide parts of tropical Asia and South America. In the hyper- and holoendemic areas of tropical Africa juveniles and adults continue to derive therapeutic benefit from chloroquine, but young children whose immunity is not yet sufficiently developed generally require treatment with alternative drugs. ► **Resistance** to the first-line alternative drugs, i.e., combinations of sulfonamides with pyrimethamine, already affects large areas in south-eastern Asia and South America, and is rising in parts of tropical Africa, necessitating the use of second-line alternative drugs which are considerably more expensive. Resistance to mefloquine and structurally related quinine occurs in Cambodia, parts of southern Vietnam and eastern Myanmar and in some parts of Thailand bordering on Myanmar and Cambodia. Here, combined treatment with artesunate or artemether with mefloquine still yields satisfactory results.

On the whole the veterinary health sector has had greater success in the development of anti-parasitic drugs than the human health sector. This is largely due to a better financial endowment of agricultural and livestock development and to the more stringent toxicological requirements governing the registration of medicaments for use in man. The situation is compounded by the fact that the development of medicaments against human parasitoses holds little attraction for the pharmaceutical industry since the main market for such drugs is in poor tropical countries.

Immunization

In many parasitic diseases there is evidence of the natural development of immunity to the specific pathogen. Such immunity rarely induces total refractoriness to reinfection, but it will restrict parasite reproduction or acceptance and induce tolerance to the pathogen. The development of

immunity is quite slow. Considerable efforts have been made in the field of immunization against parasitic diseases, especially against those caused by ► [protozoa](#). In bovine babesiosis, attenuated live *Babesia bigemina* is being used for inoculation of livestock. The resulting immunity is satisfactory, but there is still significant mortality associated with vaccination which is, on balance, economically acceptable. Such approaches are not feasible in human parasitic diseases except for agents with low virulence, e.g., *Leishmania major*.

Although immunization holds substantial promise in the control of many parasitic diseases and the progress in gene technology and polypeptide synthesis is likely to pave the way to economically acceptable products, there is still a long and arduous way to go before well-tolerated and reliable vaccination with more than palliative activity will become a reality in the control of parasitic diseases.

Clinical Relevance

Diagnostic and therapeutic measures have direct clinical relevance. Other disease control measures have indirect clinical relevance inasmuch as they are geared to the reduction of the community's disease burden, and thus a lessening of the pressure on the health services.

Disease Control, Planning

An almost universal shortage of resources, particularly marked in tropical developing countries, renders the simultaneous control of all major parasitic diseases difficult in most areas of the world. The available resources must therefore be used to address important issues with a reasonable prospect of success. Parasitic infections may be important and if the disease causes severe symptoms and kills humans or livestock people will be aware of it. Other parasitoses, however, though less spectacular, may cause even more damage on

account of their wide distribution, but public awareness may be low due to the disease's unobtrusive manifestations.

The shortage of resources and competition for those available make it necessary to set priorities on the basis of human suffering and death, or on economic loss caused by particular diseases of man or domestic animals. Many such diseases are important obstacles to development but their impact needs to be quantified in terms of disease-associated loss in order to provide a solid basis for priority ranking by governments or other interested groups. Public awareness of the disease in question may influence priority selection via political pressure and may promote community participation, but there is a risk that priorities so selected may not represent the most appropriate choice.

Once the control of a particular disease or group of diseases has been tentatively allocated high priority, the time has come to review the existing approaches that seem to be feasible in the local situation. Knowledge of the local epidemiological features and earlier experience in control within or near the area will be an asset. The feasible approaches and the specific measures required to implement them need to be projected, on a provisional basis, in terms of requirements for resources, skills, infrastructure and expected results. At this stage, or earlier, it may be necessary to strengthen epidemiological information.

After the feasibility of possible approaches has been scrutinized the preliminary objectives should be determined. These may range from elementary forms of control for the prevention of death from parasitic disease(s) to the complete elimination of the parasitosis from a particular area, country or geographical region. The setting of the objectives should be realistic and take into account the available resources. A staged procedure may be envisaged that permits the future upgrading of objectives in keeping with the growth of resources and general development.

Provisional objectives should then be put to the test in realistic feasibility studies to be undertaken under qualified technical guidance through

the service structure that is expected to be ultimately responsible for the implementation of the control activities. There is little room for so-called pilot projects since they usually operate with relatively greater resources, more qualified and more motivated personnel, and much higher staffing levels than those ultimately available to the large-scale control programme. Results from pilot projects should therefore not be used for the extrapolation of the probable impact of more extensive routine operations. Feasibility studies of single or combined approaches will permit the validation of approaches as well as technical adjustments to improve their efficacy. Such studies will also clarify requirements in terms of financial and manpower resources, training, equipment and supplies, logistics, mechanisms of evaluation and remedial action, and will provide the elements for determining cost-effectiveness.

In the light of feasibility studies, which need to be done in each major epidemiological and operational stratum, it will be possible to conclude whether the provisionally set objective can be reached with the available resources, whether the objective should be upgraded or downgraded or, in the worst of cases, whether attempts at any form of control would be futile under the present circumstances. Some thought should also be given to the capability of sustaining the control effort in the future when prevalence and/or incidence of the disease have been reduced since potentially infective reservoirs will in most situations still be present and cause serious repercussions with any slackening of the control effort. For this reason it may be more appropriate to use an existing general service structure (with technical backup and guidance from a specialized group) rather than a vertical, disease-specific service structure which is subject to political and budgetary vagaries and often lacks popular support. Control of parasitic diseases of man can be incorporated in the development and delivery of general health care, while livestock health can become part of community development activities. This approach would promote community understanding and involvement which are recognized as essential prerequisites for sustained effort and success.

Preliminary and intermediate feasibility assessment and the scrutiny of the inventory of requirements are followed by the preparation of a master plan for the control of a specific disease or group of diseases. Its successful implementation will largely depend on continuous and well-qualified technical guidance and evaluation, timely recognition of technical and administrative problems, and rapid remedial action.

Current strategies for the control of widespread and economically important human diseases such as ► [malaria](#), schistosomiasis and filariasis are described under the respective headwords.

Remote sensing by meteorological satellite technology is currently being developed as a tool for forecasting epidemics of mosquito-borne diseases. The application holds particularly high promise for areas where epidemics are known to occur as a result of cyclical changes of rainfall (e.g., the Sahel zone of Africa).

Although providing promising leads, efforts directed to the development of vaccines against ► [malaria](#) and schistosomiasis have so far not been successful enough to make projections for the availability of operationally deployable products in the immediate future.

Disease Control, Strategies

General Information

Parasitoses are widespread in the animal kingdom and in plants, causing a wide spectrum of pathologic effects ranging from little more than commensalism to severe, even fatal disease. Many parasitic diseases cause considerable suffering and have an important impact on human health, and on livestock and crop production. Some parasitic diseases have a relatively low incidence but show high severity and a potential for producing epidemic outbreaks. Others are widespread, rarely causing gross pathology, but sapping the strength and health of those affected. The mode of transmission also shows considerable variety, ranging from direct contact to obligatory passage through

several host species. The distribution of such hosts and environmental factors may therefore limit the occurrence of specific parasitoses. Thus some parasitic diseases are cosmopolitan while others may be restricted to very small ecological niches, with many nuances between these extremes. Some parasites have a rather wide choice of vertebrate hosts, others are highly stenoxenic. In addition, naturally ► [acquired immunity](#) may modify the manifestations of many parasitoses and lead to age-specific patterns of disease.

The detrimental impact of many parasitic diseases makes their control desirable if not indispensable in the interests of health and economy. The great variety of parasitic diseases and of the factors involved in their transmission requires widely different control approaches and strategies tailored to the specific epidemiological conditions and the goals of intervention.

In planning control strategies, it is helpful to classify the various parasitic diseases of man and other animals, irrespective of the causative species' taxonomic standing, into those affecting only humans (► [Anthroponoses](#)), those affecting only other animals (► [Zoonoses](#)), and those affecting both man and other animals (► [Anthropozoonoses](#) or ► [Zooanthroponoses](#)). (Major representatives of the three groups are listed under the respective headwords in order to facilitate an appreciation of the wide range of causative agents and the modes of transmission involved.) In the majority of parasitic diseases, the causative organism's life cycle provides the essential elements for developing a control strategy. Such strategies invariably aim at the interruption or reduction of transmission at vital points.

Approaches to the control of parasitic diseases are based, essentially, on an analysis of the biological system characteristic of the given parasite species, the determination of targets of intervention, the critical consideration of measures suitable for such intervention, and an inventory of available experience in the control of parasitoses.

Some measures directed against parasitic diseases may exert a non-target environmental

impact that needs to be considered in the planning of control activities. This may require environmental compatibility studies before clearing specific methods for wider application.

In all human parasitoses with gross pathology, e.g., ► [malaria](#), ► [visceral leishmaniasis](#), (► [Kala Azar](#)), African and ► [American trypanosomiasis](#), onchocerciasis and ► [lymphatic filariasis](#), clinical relevance is the motor for developing and enacting disease control strategies. These aim at improving human health and reducing disease incidence or prevalence. Similar considerations apply to diseases affecting livestock, where also economic aspects play a substantial role.

Disease Control, Targets for Intervention

Knowledge of the parasite's life cycle is a prerequisite for determining feasible targets of control intervention. However, before such knowledge became available it was not rare for communities afflicted or threatened by certain parasitic diseases to take, empirically or intuitively, appropriate measures such as the prohibition of pork as a means of avoiding trichinosis, the siting of habitations to evade ► [malaria](#) or the use of *Cinchona* bark as a febrifuge.

A rational approach to the control of parasitic diseases requires a full knowledge of potential targets. Measures directed against such targets may be practical, i.e., feasible and effective with currently available means and technology. Other targets may be too elusive for basing a strategy on their successful control. These are, nevertheless, worthy of exploration since a multifaceted approach to disease control usually offers better prospects for success than the deployment of a single measure.

Disease control is, by definition, clinically relevant. Community participation in disease control programmes depends largely on the visibility of results. Effective treatment is usually the best advertisement for a control programme and promotes the understanding for, and acceptance of,

other programme activities. Programmes without a therapeutic component are generally unpopular. In order to be viable, programmes for the control of acutely life-threatening diseases, e.g., malaria in areas with *P. falciparum*, require an efficient mechanism for the rapid and competent management of severe and complicated cases.

Disinfection

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *de* = away; *inficere* = affecting.

Mode to eliminate agents of parasites or other agents of diseases by chemical compounds.

Dispharynx

Genus of the nematode family Acuariidae, which parasitize at the walls of the stomach of birds.

Dispharynx nasuta

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species belongs to the group of nematodes and is found worldwide in the proventriculus and gizzard of passerine birds (e.g., *Paroaria coronata*). It is claimed to be identical with the described species *D. spiralis* and/or *D. pavonis*, which were also found in passerines (e.g., *Passer domesticus*) but also in chicken (*Gallus gallus*).

Dixenous Development

Many parasites have two (dixenous development) or more (► [Heteroxenous Development](#)) different hosts during their life cycle: a ► [final host](#) (where the sexual phase proceeds), and an intermediate host (with continuing asexual reproduction) or a ► [paratenic host](#), inside which no development occurs but only an accumulation of infectious stages. This alternation of hosts may be facultative or obligatory.

DNA-Synthesis-Affecting Drugs I: Alkylation Reactions (Achim Harder)

Structures

Figure 1.

Nitroimidazoles

Important Compounds

Metronidazole, Nimorazole, Ornidazole,
Tinidazole.

Synonyms

Metronidazole: SC-32642, Artesan, Flagyl I.V., Clont, Arilin, Cont, Danizol, Deffamon, Fossyol, Gineflavir, Klion, Orvagil, Sanatrichom, Trichazol, Trichocide, Tricho Cordes, Torgyl Forte, Tricho-Gynaedron, Tricocet, Trivazol, Vagilen, Vagimid.

Nimorazole: N-2-morpholinoethyl-5-nitroimidazole, Nitrimidazine, K 1900, Acterol, Esclama, Naxofen, Naxogin, Nulogyl, Sirdedi, Radanil, Rochagan.

Ornidazole: Tiberall.

Tinidazole: CP 12574, Fasigin, Fasigyn, Pletil, Simplotan, Sorquetan, Tricolam.

Clinical Relevance

The 5-nitroimidazoles (Fig. 1) exert a wide variety of activities against different pathogens. Their antibacterial activity is useful in different indications. Thus, they are useful against obligatory anaerobic intestinal bacteria, intra-abdominal gynaecological infections, aspiration pneumonia, superinfected bronchial carcinomas, brain abscesses, *Bacteroides fragilis* infections, gut wall necrosis as well as polymicrobial pelveoperitonitis. The antibacterial activity of metronidazole is also useful in the treatment of ► [Dracunculus medinensis](#) infections. Moreover, 5-nitroimidazoles are applied in chronic non-bacterial diseases of the intestine like Morbus Crohn. In addition, metronidazole or tinidazole are effective in the treatment of peptic ulcers in combination with omeprazole (lansoprazole or pantoprazole) and clarithromycin (with or without amoxicillin).

5-nitroimidazoles are in addition useful in protozoal infections caused by ► [Giardia lamblia](#), ► [Trichomonas vaginalis](#), ► [Entamoeba histolytica](#) (Table 1), in urogenital infections caused by ► [T. foetus](#) in cattle, as well as in intestinal trichomoniasis, giardiasis and ► [amoebiasis](#) in dogs, cats and monkeys. The drug has additional activities against ► [Blastocystis hominis](#) in vitro and in vivo and ► [Balantidium coli](#) infections of pigs.

DNA-Synthesis-Affecting Drugs I: Alkylation Reactions (Achim Harder), Fig. 1 Structures of drugs affecting DNA-synthesis by alkylation reactions

The antiprotozoal action of 5-nitroimidazoles is directed against *G. lamblia* ► **trophozoites** and cysts in the duodenum, against *T. vaginalis* trophozoites in vagina, cervix, urethra, epididymis, prostate and in *E. histolytica* infections against trophozoites (minuta forms) in the phase of ► **binary fission** and cysts in the intestinal mucosa and trophozoites (magna forms) in liver and other extraintestinal organs. The activity against *B. coli* is directed against the intestinal trophozoites which divide by binary fission and cysts in the faeces.

Molecular Interactions

The antibacterial action of metronidazole relies on its activation in anaerobic bacteria (*Bacteroides*, *Clostridium*) mediated by pyruvate-ferredoxin-oxidoreductase (PFOR). Metronidazole is generally not toxic to mammalian cells, because they lack electron transport proteins like PFOR with sufficiently negative redox potential for drug activation. The biochemical target of 5-nitroimidazoles is also the enzyme PFOR in *Giardia*, *Trichomonas* and *Entamoeba* (Fig. 2). In *T. vaginalis* PFOR is located in the

^fBenzimidazole, suitable alternatives to 5-nitroimidazoles

► **hydrogenosomes**. Comparison of the genes from *E. histolytica*, *T. vaginalis* and ► *G. lamblia* encoding PFOR show 35–45 % sequence identity. The PFOR from these parasites are dimeric or tetrameric proteins of 240 kDa subunits. 5-nitroimidazoles exert their activity only after the reduction of the nitro group by PFOR which occurs in single electron steps (in total four electrons) and results in the formation of a hydroxylamine derivative. The formation and disappearance of the nitro-free anion radical could be detected in ► **trichomonads** (Fig. 2). Until now there is only indirect evidence for cytotoxicity of the intermediate nitroso-free radicals and hydroxylamines. It is presumed that the interaction of toxic intermediates with various cellular

macromolecules (DNA, proteins, membranes) leads to an irreversible cellular damage by DNA-alkylation. Indeed, there is a correlation between the reduction of the nitro group of metronidazole and DNA damage in-vitro and in-vivo.

Resistance

PFOR is in the centre of the resistance mechanism in *G. duodenalis* resulting in reduced production of toxic radicals by decreased PFOR activities. Indeed, in *T. vaginalis* there is a correlation between increased metronidazole-resistance and decreased activity of the PFOR and hydrogenase. Besides PFOR in *T. vaginalis* ferredoxin (Fd) also seems to play an important role in the resistance mechanism. Thus, in metronidazole-resistant

**DNA-Synthesis-Affecting
Drugs I: Alkylation
Reactions (Achim
Harder), Fig. 2** Model of
the mechanism of action of
Metronidazole and other
5-nitroimidazoles

T. vaginalis a decrease of intracellular Fd levels by 50 %, a decrease of Fd mRNA levels by 50–65 % and a reduced transcription of Fd gene can be observed. Moreover, there is a correlation between resistance and the appearance of point mutations in the 5' flanking sequences of the gene. Two mutations could be identified with a reduced binding affinity of a 30 kDa protein to a 28 bp region within the mutated region upstream of the Fd gene. Thus, metronidazole resistance strongly correlates with an altered regulation of the Fd gene transcription. The limitation of the ability of the cell to activate metronidazole by reduced gene transcription finally results in decreased intracellular levels of Fd, so that metronidazole is less efficiently reduced to its cytotoxic form.

There is an alternative hypothesis of the resistance mechanism in *T. vaginalis* in which a half-type P-glycoprotein should be overexpressed by a mechanism other than gene amplification.

However, there is no clear correlation between levels of expression of the gene for this putative transporter protein and levels of resistance. Thus, the role of this gene in resistance remains doubtful.

Furazolidone

Synonyms

3-(5-nitrofurfurylideneamino)-2-oxazolidinone, NF180, Furovag, Furoxane, Furoxone, Giarlam, Giardil, Medaron, Neftin, Nicolen, Nifulidone, Ortazol, Roptazol, Tikofuran, Topazone.

Clinical Relevance

This drug is active against *Giardia lamblia* (Table 1). The action is directed against *G. lamblia* trophozoites in the small intestine which divide by binary fission.

Molecular Interactions

The enzyme PFOR seems to be of great importance in the furazolidone action. The reduction of this nitro compound in vivo to cytotoxic products is assumed to be similar to that of 5-nitroimidazoles (Fig. 2). The reduction potential of furazolidone is regarded as being even greater than that of metronidazole. An additional reduction mechanism of furazolidone via an NADPH/NADH oxidase to its nitroanion radical is also in discussion.

Resistance

The molecular mechanism of furazolidone resistance is unclear to date. An involvement of thiol detoxification pathways is discussed. But any correlation between a decrease in furazolidone sensitivity and an increase in thiol cycling in *G. lamblia* is very doubtful since these parasites lack the enzymes of ► [glutathione](#) metabolism.

Primaquine/Pamaquine

Synonyms

Primaquine: 8-(4-amino-1-methylbutylamino)-6-methoxyquinoline, SN 13272.

Pamaquine: Aminoquin, Beprochine, Gamefar, Plasmochin, Plasmoquine, Praequine, Quipenyl.

Clinical Relevance

Both drugs belong to the chemical class of 8-aminoquinolines. Pamaquine was discovered in 1924, primaquine was introduced in 1950. Primaquine is a very effective prophylactic antimalarial agent and very effective in preventing relapses of ► [malaria](#) so that it can be used for a radical cure (► [Haem\(oglobin\) Interaction](#), Table 1). Exoerythrocytic stages of ► [malarial parasites](#) in the liver (sporozoites, ► [hypnozoites](#), schizonts) and the erythrocytic gamonts get severely damaged (► [Haem\(oglobin\) Interaction](#), Fig. 2). Primaquine has an additional influence on the ► [sporogony](#) in the mosquito vector, however, it has no effect on erythrocytic schizonts (parasitic stages responsible for fever). Besides the

antimalarial activity primaquine shows an additional activity against *Theileria sergenti* infections.

Molecular Interactions

Primaquine is presumably metabolised in vivo to products including 5,6-quinoline diquinone which structurally resembles hydroxynaphthoquinones. It is therefore assumed that the respiratory chain of the parasites is disrupted and the pyrimidine nucleotide synthesis is inhibited. In an alternative theory the generation of free radicals during the primaquine interaction with the respiratory chain is believed to be of great importance.

Oxamniquine

Synonyms

Mansil, Vansil, Vancil.

Clinical Relevance

Oxamniquine was introduced in 1973. The antitrematodal activity is directed only against *Schistosoma mansoni*. Oxamniquine has no activity against ► [S. haematobium](#) or ► [S. japonicum](#) (► [Membrane-Function-Disturbing Drugs](#), Table 2).

Molecular Interactions

The in vitro activity of oxamniquine is very similar to that of the structurally related hycanthone. Oxamniquine leads to a delayed death of schistosomes until day 14. Thereby, an in vitro exposure of only 1 h is sufficient for the delayed death of the worms. Because the worm motility is increased at oxamniquine concentrations comparable to hycanthone, an anticholinergic action of oxamniquine was formerly proposed. However, this hypothesis is disproved in the meantime. Indeed, it could be shown that nucleic acid synthesis becomes irreversibly inhibited in drug-sensitive worms, in drug-resistant worms, in *S. japonicum* and in immature worms. The inhibition is more pronounced in male than in female schistosomes. The mode of action of hycanthone and oxamniquine is summarised in

**DNA-Synthesis-Affecting
Drugs I: Alkylation
Reactions (Achim
Harder), Fig. 3**

Proposed
mechanism of action of
hycanthon and
oxamniquine

Fig. 3 according to the model of Cioli et al. 1995. At first hycanthon (and also oxamniquine) is converted to an ester (sulphate, phosphate or acetate) by a specific schistosomal enzyme. Thereafter, the ester spontaneously dissociates resulting in the formation of an electrophilic reactant which is capable of alkylating schistosomal DNA. Thus, the initial drug esterification is the only enzymatic step in the whole pathway (Fig. 3). The validity of this model is supported by experiments using the N-methylcarbamate esters of hycanthon. These hycanthon esters have been shown to be equally active against sensitive and resistant worms, since the first enzymatic esterification step can be surmounted by these hycanthon esters. As a result covalent binding of hycanthon and oxamniquine to macromolecules including DNA occurs in vitro. In female and in immature schistosomes binding of hycanthon and oxamniquine to DNA is diminished compared to males. Adducts of hycanthon with guanosine residues of schistosomal DNA are formed.

ATP, Mg^{++} and another unknown small molecule are cofactors during the esterification step by the schistosomal enzyme. The activity of this enzyme can be restored by sulfate ions. Thus, this enzyme may function as a sulfotransferase with a molecular weight ranging from 30 to 35 kDa. The real function of this sulfotransferase is still unknown. A possible detoxifying function is discussed as well as an involvement in modifying male and female steroid hormones. Such a sulfotransferase is presumably also present in *S. haematobium* and *S. japonicum*. However, structural differences of the sulfotransferases between the different *Schistosoma* spp. may be responsible for different binding of hycanthon and oxamniquine to this enzyme. While there is a strong binding of both drugs to *S. mansoni* sulfotransferase, only hycanthon can be bound by *S. haematobium* sulfotransferase. The sulfotransferase of *S. japonicum* is even unable to bind hycanthon or oxamniquine.

Additional Features

There are also differences in the mutagenicity between hycanthone and oxamniquine. Oxamniquine has very low mutagenic activity compared to hycanthone. The mutagenicity of hycanthone is due to production of frameshift mutations as a consequence of its ability to intercalate between DNA base pairs resulting in an unwinding and distortion of the double helix. Therefore, hycanthone has been withdrawn as an antischistosomal drug. Oxamniquine also has some minor intercalative properties which are not enough for strong mutagenic effects.

Resistance

Resistance against hycanthone and oxamniquine is controlled by a single, autosomal, recessive gene. Resistant schistosomes lack the activity essential for antischistosomal effects of oxamniquine in sensitive worms, because the enzymatic esterification step is missing in resistant parasites similar to the susceptible *S. japonicum*.

DNA-Synthesis-Affecting Drugs II: Interference with Purine Salvage

Structures

Figure 1.

Diloxanide

Synonyms

2,2-dichloro-4'-hydroxy-N-methylacetanilide, Furamide, Entamide, Ame-Boots.

Clinical Relevance

Diloxanide is exclusively used as fluorate ester. The antiprotozoal activity is directed against ► **trophozoites** and lumen cysts of ► *Entamoeba histolytica* (► **DNA-Synthesis-Affecting Drugs I**, Table 1). Diloxanide has only minor activity in acute ulcerative intestinal ► **amoebiasis**. Combinations of diloxanide with 5-nitroimidazoles,

Diloxanide

Allopurinol

Arprinocide

DNA-Synthesis-Affecting Drugs II: Interference with Purine Salvage, Fig. 1 Structure of drugs affecting DNA-synthesis by interfering with purine salvage

emetine or chloroquine for the treatment of amoebic dysentery and liver abscesses can be very useful.

Molecular Interactions

It is suggested that diloxanide interferes with the purine salvage system by impairing adenine incorporation during the RNA-synthesis in *E. histolytica*.

Allopurinol

Synonyms

Allopurinol, Zyloric.

Clinical Relevance

Allopurinol is in medical use against ► *Leishmania* spp. In addition, it has experimental activity against ► *Trypanosoma* spp. (Table 1).

xxx = high efficacy at least against some developmental stages, and diverse species; xx = partially effective (regarding developmental stages and diversity of species); x = slightly effective; E = experimentally effective; (1) in blood (acute phase); (2) in liquor (late phase); (3) 1997 for *visceral leishmaniasis*, 2005 for *cutaneous leishmaniasis*; (4) for *visceral leishmaniasis*, potentially affordable alone or in combination; possible replacement for antimony

Furthermore, allopurinol is clinically used in the treatment of gout as urikostatic drug.

Molecular Interactions

The antiprotozoal mode of action against *Trypanosoma cruzi* and *Leishmania* spp. relies on the metabolism of allopurinol to adenosine nucleotide analogues. These are then incorporated into RNA with the result that the growth rate of sensitive parasites is significantly reduced.

The mode of action in gout is quite different from the antiprotozoal action presumably by the inhibition of xanthine oxidase.

Arprinocide

Synonyms

9-(2-chloro-6-fluorobenzyl)adenine, MK-302, Aprocox.

Clinical Relevance

Arprinocide exhibits good anticoccidial and anticoccidiostatic activity (► [DNA-Synthesis-Affecting Drugs IV](#), Table 1). Its activity against *Eimeria tenella* is weaker compared to that against other ► *Eimeria* spp.

Molecular Interactions

Arprinocide is simultaneously a purine and pyrimidine analogue. The activity is directed against sporozoites, merozoites and first generation schizonts. The main mechanism of action remains unclear. Many pyrimidine nucleotide-requiring enzymes are inhibited. Also, the uptake of hypoxanthine and guanine in infected eukaryotic cells is inhibited. The anticoccidial activity of arprinocide is mediated by the N-1 oxide metabolite. Interestingly, the N-1 oxide metabolite itself is not a potent inhibitor of the biochemical pathways in spite of the very potent in vitro and in vivo activity. Electronmicroscopically, a vacuolization and degeneration of intracellular membrane systems of ► *coccidia* can be observed.

Mode of Action

Figure 1.

Structures

Figure 2.

Melarsoprol

Synonyms

Melarsen oxide, Mel B, Arsobal.

Clinical Relevance

Melarsoprol was explored in 1949 and was the drug of choice for late phase of infections with *T. b. gambiense* and *T. b. rhodesiense* until 1990 (Table 1). An intravenous application is necessary with 3.6 mg/kg b.w. in three to four series of four injections separated by at least 1 week. Melarsoprol possesses serious toxic side effects

such as reactive encephalopathy in 5–10 % of the cases with a mortality rate of 1–5 %. In veterinary medicine melarsoprol is exceptionally used against *T. equinum* in horse. It has only low efficacy against *T. simiae* in pigs.

Molecular Interactions

Melarsoprol is a trivalent organic arsenical. The activity is directed against ► *trypomastigotes* in the liquor. An inhibition of trypanosomal pyruvate kinase (PK) as the mode of action was proposed very early. There is a loss of motility of drug-treated trypanosomes, and cell lysis occurs within minutes. However, there is no correlation between melarsoprol-induced lytic effects and inhibition of pyruvate kinase. In the meantime trypanosomal phosphofructokinase (PFK) ($K_i < 1 \mu\text{M}$) and fructose-2,6-bisphosphatase ($K_i = 2 \mu\text{M}$) are found to be better melarsoprol targets than PK ($K_i = 100 \mu\text{M}$), resulting in a complete inhibition of the formation of fructose-2,6-bisphosphate.

As an alternative hypothesis the inhibition of trypanothione reductase (TR) by complexation of trypanothione with melarsoprol or melarsen oxide is discussed (Fig. 1). This complexation would lead to a complete disturbance of the redox balance within the trypanosomal cell. An inhibition of TR would have lethal effects on trypanosomes. The melarsen-trypanothione adduct Mel T has a stability constant of $1.05 \times 10^7 \text{ M}^{-1}$. The inhibition of ► *glutathione* reductase and the *T. b. brucei* TR is characterised by K_i values of 9.6 and 17.2 μM , respectively.

The main argument against TR as target for melarsoprol is the 18-fold-higher K_i value for the inhibition of TR compared to PFK. Furthermore an association of trypanothione with trivalent arsenicals is much weaker than that of 2,3-dimercaptopropanol or lipoic acid. Thus, the selective advantage of the presence of trypanothione in kinetoplastids has remained speculative until now. Melarsoprol is very efficient in forming adducts with a variety of dithiols (coenzyme dihydrolipoate, some proteins with cysteine residues). A nonspecific inhibition of many different enzymes may explain many severe toxic side effects of melarsoprol.

DNA-Synthesis-Affecting Drugs III: Interference with Polyamine Metabolism and/or Trypanothione Reductase, Fig. 1 Trypanothione metabolism and inhibition by drugs in kinetoplastid ► [protozoa](#)

Resistance

Resistance against melarsoprol is a general serious problem in the treatment of ► [sleeping sickness](#). Resistant trypanosomes are not lysed by melarsoprol or by the chemically related melarsen oxide at concentrations even higher than 100 μ M. A significant decrease in free trypanothione levels could not be detected in

resistant strains, whereas a rapid decrease in trypanothione levels was described in sensitive strains just before lysis. Isolated TR from resistant or sensitive strains was shown to be equally inhibited by the melarsoprol-trypanothione adduct Mel T, indicating that TR may not be a validated target for melarsoprol.

^aIn blood (acute phase)

^bIn liquor (late phase)

A new hypothesis for the resistance mechanism of melarsoprol relies on alterations of melarsoprol transport in resistant trypanosomes with a possible participation of drug efflux mechanisms similar to multidrug-resistant cancer cells. Indeed, there is no lysis of melarsoprol resistant strains in the presence of melarsoprol plus Ca⁺⁺ channel-blockers (verapamil, diltiazem or nifedipine). The mechanism of this so-called melarsen-based drug resistance in trypanosomes is due to their absolute purine requirement. Two non-identical purine transporters P1 and P2 have been identified in trypanosomes. The transporter P2 is responsible for the uptake of melarsen or melarsoprol, adenine and adenosine. The melarsen oxide-induced trypanosomal lysis can be inhibited by adenine, adenosine and dipyrindamol, an inhibitor of nucleoside transport in mammalian cells. Adenine, adenosine and melarsoprol thus compete for the transporter P2 in *T. b. brucei*. There is a reduction of the rate of adenosine transport by 80 % in melarsen oxide resistant *T. b. brucei* compared to sensitive strains indicating a possible lack of transporter P2 in melarsen oxide-resistant *T. b. brucei*.

There is high cross-resistance between melarsoprol and the diamidine berenil in strains

of *T. b. rhodesiense* clinical isolates, *T. b. brucei* veterinary isolates, in laboratory strains of *T. evansi* and others, but low cross-resistance between melarsoprol and pentamidine. Cross-resistance between melarsoprol and pentamidine can be correlated with differences in their uptake rates in *T. b. brucei*.

Resistance against the so-called phenyl-based tryparsamide has been known since the 1930s. Interestingly, melarsen-resistant strains are sensitive to phenylarsenoxide and there is no cross-resistance between melarsoprol and phenylarsenoxide. This fact may be explained by the existence of another transporter (P1) for adenosine and inosine, which, however, does not transport melarsen oxide. Thus, phenylarsenoxide-induced lysis of trypanosomes cannot be inhibited by adenine or adenosine in sensitive trypanosomes which supports the idea of different uptake mechanisms of melarsoprol and phenylarsenoxide into trypanosomes.

Eflornithine

Synonyms

DFMO, DL- α -difluoromethylornithine.

Clinical Relevance

Eflornithine was introduced in 1982 for the treatment of West African sleeping sickness (*T. b. gambiense*). It is active against early and late stages of *T. b. gambiense* (► [DNA-Synthesis-Affecting Drugs II](#), Table 1). Eflornithine is characterised by a remarkably great safety index but possesses a relatively weak overall efficacy and a short duration of activity. An intravenous application is necessary with a dosage of 400 mg/kg b.w. per day in four equal doses every 6 h for 14 days. Eflornithine also has activity against *T. b. brucei* and *T. congolense* and against multiresistant strains of *T. b. gambiense* (bloodstream forms and liquor forms). For the activity of eflornithine an intact immune system is necessary. A disadvantage of eflornithine is its ineffectivity against *T. b. rhodesiense* infections.

In addition eflornithine exerts some activity against leishmania and different opportunistic parasites such as ► *Pneumocystis carinii*, *Cryptosporidium* in ► [AIDS](#) patients as well as in vitro or in vivo activity against exoerythrocytic schizonts of *Plasmodium berghei*. Moreover, there is a report about some antitumor activity.

Molecular Interactions

Eflornithine is a fluorinated amino acid derivative with zwitterionic properties. Under physiological conditions, it is poorly absorbed and rapidly excreted in the urine. The mechanism of action is well established and the *T. brucei* ornithine decarboxylase (ODC) is a fully validated therapeutic target. In trypanosomes, which are fully dependent on their own polyamine biosynthetic machinery, DFMO acts as an irreversible “specific suicide” inhibitor of ornithine decarboxylase ODC (Fig. 1) by formation of a covalent adduct between the decarboxylated and defluorinated DFMO and the residue 360 in ODC. As a result the trypanothione biosynthesis is inhibited (Fig. 1) and also the biosynthesis of the ► [polyamines](#) putrescine, spermidine and spermine. Thus, an in vitro and in vivo depletion of the putrescine and spermidine from dividing (► [Binary Fission](#)) *T. brucei* trypomastigotes in the blood and liquor occurs. As a result of the inhibition of polyamine metabolism many

different cell functions are impaired, e.g., the differentiation of trypanosomes into non-dividing short stump-like forms. In addition, DFMO-treated *T. brucei* are kept in the dormant G1 phase by loss of ODC activity. Moreover, the synthesis of ► [variant surface glycoprotein](#) is inhibited. The selective toxicity of eflornithine must be seen in direct connection with the slow turnover of ODC of *T. brucei* compared to the mammalian enzyme. Mouse ODC possesses an extra 36 amino acid peptide at the C-terminus (PEST sequence) triggering in vivo degradation of mammalian ODC. This is responsible for the short half-life of ODC of about 20 min in mammalian cells. By contrast the in vivo half-life of *T. brucei* ODC is longer than a day because of the lack of the PEST sequence. A further consequence of the DFMO-induced increased levels of adenosylmethionine may be an inappropriate methylation of proteins, nucleic acids or lipids. The lack of polyamines which are essential for the trypanothione synthesis may itself be sufficient for the explanation of the death of trypanosomes caused by DFMO.

Resistance

Until now there are no reports about DFMO resistance because of the short time of its clinical use. Experimental resistance was examined in vitro using either procyclic forms of trypanosomes or naturally resistant strains. However, the mechanism of resistance on the molecular level remains unclear. In some resistant strains a reduced DFMO-uptake could be observed accompanied by an increase of intracellular concentrations of ornithine, whereas in other resistant strains no such reduced DFMO-uptake was detectable. There is no increased ODC activity in *T. brucei rhodesiense* field strains. However it could be shown that the ODC in DFMO-resistant *T. gambiense* possesses a rather short half-life compared to ODC in DFMO-susceptible trypanosomes which have an extraordinarily long half-life. As a result of the rapid in vivo turnover rates and synthesis of new active ODC molecules in resistant strains DFMO-inhibited ODC molecules are rapidly replaced. Thus, cells with a rapid ODC turnover are much less affected by the inhibition

of ODC. A further difference between DFMO resistant and -susceptible trypanosomes seems to be the different increase in the adenosine methionine content by DFMO. Thus, in resistant strains an only sevenfold increase is observable compared to the up to 100-fold increase in sensitive strains. There also seems to be a correlation between DFMO resistance and decrease in adenosine methionine synthetase.

Pentamidine/(Hydroxy)stilbamidine

Synonyms

Pentamidine isethionate, 4,4'-diamidinodiphenoxypentane, M&B800, RP2512, Lomidine, Pentacarinat.

Clinical Relevance

The diamidines are in clinical use since 1937. Pentamidine is a therapeutic and prophylactic drug against bloodstream forms in sleeping sickness (Table 1). It is, however, active only against early stages of *T. b. gambiense* infections, but not against the liquor forms. Seven to ten intramuscular injections are necessary with 4 mg/kg b.w. daily or on alternative days. Pentamidine also exhibits activity against *Leishmania donovani* and *L. chagasi* in spleen, liver and skin, but has only minor activity against the American mucocutaneous leishmaniasis (*L. brasiliensis*). Furthermore pentamidine possesses antibabesial activity and is becoming increasingly important in replacing chloroquine against infections with ► *Babesia* spp. Pentamidine has no effect against *Trypanosoma cruzi*. (Hydroxy)-stilbamidine has a similar antiprotozoal spectrum and is useful in antimonial-resistant Kala-Azar (*L. donovani*).

The main indication for pentamidine is its activity against opportunistic parasites. It is the drug of choice for the *Pneumocystis carinii* ► pneumonia in AIDS patients. Moreover, pentamidine has some antifungal activity against North American blastomycosis (*Blastomyces dermatididis*).

Molecular Interactions

The mechanism of action of pentamidine is directed against trypomastigotes in the blood which divide by binary fission. Following the uptake into the bloodstream forms of *T. b. brucei* via a carrier-mediated process the binding of pentamidine to nucleic acids is believed to be of great importance. Recently a pentamidine-dodecanucleotide-complex could be identified by cocrystallisation. Drug binding occurs in the 5'-AATT minor groove region of the duplex, preferentially to the minor grooves of the ► kinetoplast DNA in *T. brucei*. Thereby, the amidinium groups of pentamidine become H-bonded to adenine N₃ atoms. As a result the kinetoplast DNA is disrupted so that dyskinetoplastic cells are generated with intact mitochondrial membranes but lacking detectable kinetoplast DNA. Pentamidine has no effects on the trypanosomal nuclear DNA.

Furthermore, a 13-fold increase in lysine and 2.5-fold increase in arginine content is induced in the trypanosomes at the therapeutic dose. Electronmicroscopically, an intercalation of diamidines into the kinetoplast DNA (kDNA) could be detected resulting in lampbrush ► chromosomes. This observation supports the proposed inhibition of DNA synthesis by diamidines. Additional nuclear aggregation in diamidine-treated trypanosomes may also explain the inhibition of ribosomal RNA synthesis. The disintegration of kDNA begins at the periphery of the ► kinetoplast, where DNA replication starts. Moreover, pentamidine interferes with the trypanothione metabolism by inhibiting the decarboxylation of S-Adenosylmethionine (Fig. 1). Because of their close structural similarity to pentamidine, (hydroxy)stilbamidine presumably has the same mechanism of action (Fig. 1).

Resistance

Resistance to diamidines is well established under field conditions. Resistant strains are characterised by a diminished ability to import pentamidine into the cells. However, it is unclear to date whether an impaired pentamidine uptake, drug efflux or drug metabolism is responsible for the mechanism of pentamidine resistance.

Diminazene

Synonyms

Berenil, Diminazene aceturate, Diminazene diacetate, Azidin, Ganasag, Trypan, Veriben.

Clinical Relevance

Berenil was originally introduced in 1955 as a trypanocide and babesiacide. It is active against *Trypanosoma b. gambiense* and *T. b. rhodesiense* (Table 1). Of especial interest is the activity against liquor forms of *T. b. rhodesiense*. Berenil is often used in chronic human infections, although it is a veterinary product. The treatment of human trypanosomiasis with berenil is recommended in cases of arsen resistance or before starting treatment with melarsoprol. In veterinary medicine berenil is used against *T. brucei*, *T. congolense*, *T. vivax* and *Babesia* spp. in cattle, sheep and goats in Africa. Higher dosages are usually necessary for curative effects against *T. equiperdum* in horses. Berenil has only minor activities against *T. simiae* in pigs, *T. evansi* in camels and cattle and *T. equinum* in horses. It should be mentioned that berenil also has experimental effectivity against ► *Leishmania* spp. (Table 1).

Furthermore, berenil has activity against ► *piroplasms* of domestic animals (*Babesia* spp. with large erythrocytic parasitic stages). It has good efficacy against *Babesia bigemina*/cattle, *B. ovis* and *B. motasi*/sheep, *B. caballi*/horse, *B. canis*/dog, *B. hepailuri*/cat. However, the drug has far less activity against *Babesia* spp. with small erythrocytic stages (*B. bovis* and *B. divergens*/cattle, ► *Theileria* (formerly *Babesia*) *equi*/horse, *B. gibsoni*/dog) and apparently no effect against *B. felis*/cat.

Molecular Interactions

Berenil as an analogue of pentamidine exerts a similar mode of action. The activity of berenil is directed against trypomastigotes in the blood and liquor. In berenil-treated *Leishmania tarentolae* the kDNA content is greatly reduced. It is reported that berenil binds to the minor groove of DNA with a higher affinity to 5'-AATT-3' than to

5'-TTAA-3'. The attachment to specific sites in DNA occurs via electrostatic and H-bond forces. In addition, it is discussed that berenil may inhibit the kinetoplast topoisomerase II in trypanosomes, resulting in the cleavage of 2 % of the minicircle DNAs in the presence of 1 μ M drug. Also a possible interference of berenil with the trypanothione metabolism by inhibiting the decarboxylation of S-Adenosylmethionine is worth mentioning (Fig. 1).

Resistance

Interestingly, there is no widespread development of berenil resistance in the field in spite of long-term use. There are reports on cross-resistance between quinapyramine, melarsomine and berenil in laboratory and field strains. The mechanism of resistance to berenil is possibly due to a diminished drug uptake by resistant trypanosomes.

Imidocarb Dipropionate

Synonyms

Carbesia, Imixol, Imizol, Imizocarb, 4A65.

Clinical Relevance

The antiprotozoal activity of this drug is directed against *Theileria* (formerly *Babesia*) *equi* and *Babesia caballi* in donkeys and mules. In addition, babesiosis of cattle may be controlled relatively easily by imidocarb.

Molecular Interactions

Imidocarb is a diamidine derivative. Thus, its action may be similar to that of berenil (► *DNA-Synthesis-Affecting Drugs III*/Fig. 1).

Quinapyramine, Homidium, Isometamidium

Synonyms

Quinapyramine: M7555, Antrycide, Triguin, Trypacide.

Homidium chloride: RD1572, Novidium, Babidium. Homidium bromide: Ethidium, Dromilac.

Isometamidium: Metamidium, M&B4180, Samorin, Trypamidium.

Clinical Relevance

Quinapyramine (Table 1) has activity against *Trypanosoma equiperdum* in horses and donkeys. Homidium and Isometamidium are used in ► [chemoprophylaxis](#) against *T. brucei evansi* in cattle, sheep and goats in Africa, and they have also activity against *T. vivax* and *T. congolense*.

Molecular Interactions

Quinapyramine probably acts indirectly by inhibition of protein synthesis by displacement of magnesium ions and polyamines from the ribosomes. Homidium bromide belongs to the phenanthridinium derivatives. Its antitrypanosomal activity has been known for about 50 years. It is routinely used for staining nucleic acids in research laboratories because it intercalates into nucleic acids. It possesses mutagenic properties. The mechanism of antitrypanosomal action of homidium is unclear. There are reports on an interference with glycosomal functions, interference with the function of an unusual AMP binding protein, on impaired trypanothione metabolism and impaired replication of kinetoplast minicircle (2 % of total minicircle become linearised by 1 µM homidium) in trypanosomes.

As isometamidium is structurally related to both – homidium and berenil, the properties and activities may be similar. Isometamidium has a great acute toxicity to mammals which is not observed with homidium or berenil. The acute toxic effects of isometamidium in mice can be reversed with atropine indicating probable inhibitory effects on acetylcholinesterase. However, the mechanism of antitrypanosomal action of isometamidium is not yet fully understood. A linearisation of 6 % of the total minicircle DNA from *T. equiperdum* at 1 µM may also contribute to the drug's action. In vitro an intercalation between the base pairs of the DNA can be observed which may explain the interruption of DNA functioning observed in vivo.

Resistance

The extensive use of homidium in the 1960s and 1970s has greatly reduced its usefulness by widespread trypanosomal resistance. The mechanism of resistance is so far unknown. The mechanism of resistance against isometamidium is presumably associated with reduced accumulation of the drug in trypanosomes. There are reports on cross-resistance between isometamidium and homidium, which supports the idea of a similar mode of action of both drugs.

Nifurtimox

Synonyms

Lampit, Bay2502.

Clinical Relevance

Nifurtimox was introduced in 1972 as a causal therapeutic drug for ► [American trypanosomiasis](#) (= Chagas disease) caused by *T. cruzi* (Table 1). It has curative effects in acute, subchronic and chronic disease. Infection-induced damages of organs, however, are not improved by this drug.

Molecular Interactions

Nifurtimox is a nitrofurfurilidene derivative. It induces a destruction of non-dividing trypomastigote bloodstream forms and intracellular amastigote tissue forms in the muscles of heart, skeleton, oesophagus and intestine, in the lymph nodes and in the nervous system. One possible action may be the inhibition of trypanothione reductase (Fig. 1). As *T. cruzi* has only low detoxification capacity, it is completely dependent on the trypanothione metabolism. As another action the generation of reactive oxygen derivatives (superoxide, H₂O₂ and hydroxyl radicals) is discussed, which cause peroxidation of lipids and damage of the nucleic acids.

Resistance

At present there are no great problems concerning clinical resistance against nifurtimox.

Benznidazole

Synonyms

Ro7-1051, Radanil, Rochagan.

Clinical Relevance

Benznidazole was introduced in 1978. It damages trypomastigote bloodstream forms and amastigote tissue forms of *T. cruzi* (Table 1). There are reports on a low efficacy against the Brazilian ► [cutaneous leishmaniasis](#).

Molecular Interactions

The activity is directed against the same stages as by nifurtimox. Probably the trypanothione metabolism becomes disturbed (Fig. 1) and an involvement of generation of free radicals similar to nifurtimox is discussed. There are additional reports on an inhibition of protein- and RNA-synthesis and a damage of DNA.

DNA-Synthesis-Affecting Drugs IV: Interference with Cofactor Synthesis

Tables 1 and 2, Fig. 1.

Structures

Figure 2.

Sulfonamides

Important Compounds

Sulfachloropyrazine, Sulfadiazine, Sulfadimethoxine, Sulfadimidine, Sulfadoxine, Sulfaguanidine, Sulfalene, Sulfamethazine, Sulfamethoxazole, Sulfametoxyypyridazine, Sulfanitrans, Sulfaquinoxaline/Pyrimethamine, Sulfaisoxazole, Sulfathiazole.

Synonyms

Sulfachloropyrazine: Cosulfa, Cosulid, Nefrosul, Prinzone, Sorilyn, Vetsulid.

Sulfadiazine: Adiazine, Debenal, Diazyl, Eskaiazine, Flamazine, Flammazine, Pyrimal, Silvadene, Sterazine, Sulfolex.

Sulfadimethoxine: Agribon, Albon, Ancosul, Bactover, Diasulfa, Diasulfyl, Dimetazina, Dinosol, Madribon, Maxulvet, Memcozine, Metoxidon, Neostreptal, Radonina, Retardon-N drops, Roscosulf, SDM.

Sulfadimidine: Sulfadimidine 33 % Forte, Sulfadimidine powder, Unidim.

Sulfadoxine: Fansil, Fanzil, in combination with pyrimethamine: Fansidar.

Sulfaguanidine: Abiguanil, Aterian, Diacta, Ganidan, Guamide, Guanil, Resulfon, Ruocid, Shigatox, Suganyl, Sulfaguine, Sulfoguenil, Enterosediv.

Sulfalene: Farmitalia, Dalysep, Kelfizina, Longum, Polycidal.

Sulfamethazine: Azolmetazin, Diazil, Dimezathine, Dimidin-R, Mefenal, Neazina, Pirmazin, S-Dimidine, S-Mez, Sulfa 25 % powder, Sulfadine, Vesadin, Vertolan.

Sulfamethoxazole: Abacin, Apo-Sulfatrim, Bactramin, Bactrim, Bactromin, Baktar, Drylin, Eltranyl, Eusaprim, Fectrim, Gantanol, Gantaprim, Gantrim, Kepinol, Linaris, Micotrim, Momentol, Nopil, Omsar, Septra, Septrim, Sigaprim, Sinomin, Sulfotrim, Sulfotrimin, Sulprim, Sumetrolim, Suprim, Tacumil, Teleprim, TMS480, Trigonyl, Trimesulf, Trimforte, Uro-Septra.

Sulfametoxyypyridazine: Davosin, Depovernil, Durox, Kynex, Lederkyn, Lentac, Midicel, Midikel, Myasul, Mylo-Sulfdurazin, Sultirene, Vines.

Sulfanitrans: Novastat, Polystat, Unistat.

Sulfaquinoxaline/Pyrimethamine: Sulka TAD, Coccex solution, single drug: Aviochina, Embazin, Dr. Hess SQX, Quinatrol, Quinel, Solquin, Sol-Quinel, S.Q., Sulfa-Nox, Sulfa-Q, Sul-Q-Nox, Sulfaquinoxaline 100 % powder, Vineland Liquid Sulfaquinoxaline.

Sulfaisoxazole: Entusil, Entusul, Gantrisin, Gantrosan, Neazolin, Renosulfan, Sosol, Soxisol, Soxo, Soxomide, Suladrin, Sulfalar, Sulfazin, Sulfum, Sulfoxol, Sulsoxin, V-Sul.

Sulfathiazole: Eleudron solution.

DNA-Synthesis-Affecting Drugs IV: Interference with Cofactor Synthesis, Table 1 Degree of efficacy of important anticoccidial drugs on various protozoan parasites

Year on the market	Drug	Apicomplexa				
		<i>Eimeria</i> (chicken)	<i>Toxoplasma gondii</i>	<i>Babesia</i>	<i>Theileria</i>	<i>Plasmodium</i>

1971	Polyethers (b)	xxx	x (a)			
1986	Narasin, Nicarbazine	xxx				
Drugs with unknown antiparasitic mechanism of action						
1960	Zoalene	xx				
	Dinitolmide (DOT)	xxx				
1976	Halofuginon (e)	xxx			xxx	xx
1993	Diclazuril/clazuril	xxx				

xxx high efficacy at least against some developmental stages, and diverse species, xx partially effective (regarding developmental stages and diversity of species), x slightly effective, E active experimentally (Haberkorn 1993; Mc Dougald 1993, 1994), R resistances arose quickly; (a) prophylactically only; (b) e.g., Monensin, Lasalocide, Madurymycin, Salinomycin, Semduramycin; Narasin

Clinical Relevance

Sulfonamides exert activities against a variety of pathogens. They possess a broad-spectrum activity against gram positive and gram negative bacteria such as *Nocardia* spp., *Chlamydia* spp., *Yersinia* spp. and atypical mycobacteria (*Mycobacterium scrofulaceum*).

The first anticoccidial sulfonamides were introduced in 1946. Sulfonamides currently used in veterinary medicine are sulfaquinoxaline, sulfadimidine, sulfadiazine, sulfadimethoxazole, sulfadoxin and others. They are characterised by

a narrow anticoccidial spectrum against ► *Eimeria* spp. residing in the small intestine (*E. acervulina*), and they have only minor activity against *E. necatrix* and *E. tenella*. Sulfaquinoxaline is used in combination with amprolium or 2,4-diaminopyrimidines or in a multidrug combination together with ethopabate and pyrimethamine (Table 1). There are also other combinations of veterinary importance (Table 2). Sulfonamides have been very useful against *Plasmodium falciparum* as single drug or in combination with pyrimethamine (sulfadoxin/

xxx highly effective, xx good effective, x low activity, E active experimentally; (a) low tolerability

pyrimethamine), because of their schizonticidal effects against both exoerythrocytic and erythrocytic stages (► [Hem\(oglobin\) Interaction](#)/Table 1, Fig. 2). In general, they have greater efficacy against *P. falciparum* compared to *P. malariae*, *P. ovale* or *P. vivax*. Other indications in which sulfonamides are used are infections with ► *Toxoplasma gondii*, ► *Pneumocystis carinii*, ► *Sarcocystis* spp., *Cystispora* spp., ► *Isospora* spp. and others. A sulfadiazine/clindamycin-combination is active against ► *Neospora caninum* in young dogs, if started very early in the disease (Table 2).

Molecular Interactions

The antiparasitic activity of sulfonamides is primarily directed against second ► [schizont](#) generations. There is also activity against first schizont generation and sexual stages (► [Hem\(oglobin\) Interaction](#)/Fig. 2). The activity of antimalarial sulfonamides such as sulfadoxin is directed against exoerythrocytic liver schizonts, erythrocytic schizonts and also oocysts in the gut of ► [mosquitoes](#) (► [Hem\(oglobin\) Interaction](#)/Fig. 2). Sulfadoxin belongs to the long-acting sulfonamides. The first hint about the mode of action of sulfonamides came from the observation

► apicomplexa

that the anticoccidial activities of sulfonamides can be reversed by paraminobenzoic acid (PABA), an intermediate in folate biosynthesis. Now it has been known for a long time that the action of sulfonamides and of sulfones like

dapsone relies on the inhibition of dihydropteroate synthase in intracellular ► *sporozoa* *Eimeria*, *Toxoplasma* and ► *Plasmodium*. Thus, the coccidial ► *folic acid* biosynthesis is inhibited by sulfonamides which is lethal to
